Case 7.—A girl, aged 1 year, had vomited, shivered, and for a time could not be roused, on April 18, 1948. On April 20 she had been admitted to hospital very ill and dyspnœic, and diagnosed as acute follicular tonsillitis and bronchopneumonia. She had been given penicillin 10,000 units intramuscularly six-hourly from April 20 to 25; sulphonamides total dosage 10 g. from April 20 to 27. A radiogram of her chest had shown nothing abnormal. She had remained febrile, but her condition had improved. On April 30 she had relapsed, with slight neck rigidity. Lumbar puncture had produced turbid C.S.F., and a stained film of the deposit showed organisms resembling *H. influenzæ*. The patient was thereupon transferred to the London Hospital.

On Admission.—Temperature 98°F, pulse-rate 100 and respirations 34 per min. She looked ill and grey, crying monotonously when roused, but rapidly sinking back into a semicomatose state, grinding her teeth, and with muscular twitchings of the face. Neck rigidity was well marked. The ear drums were injected. Hb 70%, white-cell count 37,800 per c.mm. (polymorphs 73%). Blood-culture produced *H. influenzæ*. C.S.F. contained 1280 cells per c.mm., protein 120 mg. and sugar 20 mg. per 100 ml., and on culture produced *H. influenzæ* (1) sensitive to streptomycin.

Treatment.—Streptomycin 500 mg. intramuscularly daily from April 30 to May 10, and 50 mg. intrathecally daily from April 30 to May 9. The C.S.F.-streptomycin level had an average range of 8–16 units per ml.

Progress.—On May 10 there was little if any clinical improvement (for temperature see fig. 1). Streptomycin was discontinued after the C.S.F. had been sterile for nine days. On May 11 a few crepitations were heard at the organism remained sensitive. In a fourth (case 9) the organism persisted in the C.S.F., and daily estimations showed a rapid diminution of sensitivity. Originally the strain was inhibited by 1 unit of streptomycin, but forty-eight hours later it grew in 400 units. At necropsy four weeks later it was still insensitive.

Results.—Of 8 patients treated with streptomycin alone 2 died and 6 recovered. Of 3 patients treated with combined therapy 1 died. Case 2 is excluded because no organism was grown from the C.S.F. or from the blood before streptomycin was given. Thus of 11 patients 3 died, giving a case-mortality of 27%. The C.S.F. became sterile within twenty-four hours of the start of streptomycin treatment in 7 cases out of 9.

CASE-RECORDS

On admission, besides a complete physical examination, every child underwent the following investigations as a routine: lumbar puncture, throat swab, blood-count, examination of urine, blood-culture, and radiography of chest. Positive findings alone are recorded. The C.S.F. was examined daily. The number of days during which *H. influenzæ* was cultured after the start of streptomycin treatment is noted in parentheses. This includes the one C.S.F. culture made from material taken immediately before the start of streptomycin treatment. The organism grown from C.S.F. was typed in every case and found to be Pittman's type B.

Case 1.—A boy, aged 9 months, had become irritable in the morning of March 12, 1947, vomited at midday, and then had a convulsion lasting an hour. For the next ten days he had been quiet and rather listless. He had been admitted to hospital on March 22 with well-marked neck rigidity. Lumbar puncture (March 20) produced turbid C.S.F. which on culture grew *H. influenzæ.* Penicillin 200,000 units intramuscularly three-hourly and sulphathiazole 1 g. four-hourly had been given from March 22 to 28 and then discontinued because the temperature had been normal for three days. The patient had relapsed in the evening of March 28, and was transferred to the London Hospital on March 30.

On Admission.—Temperature 101°F, pulse-rate 140 per min. He did not look very ill. He followed objects with his eyes and grasped with his hands. There was well-marked head retraction and neck rigidity. The fontanelle was not tense. Pus was aspirated from an abscess in the thigh (? site of penicillin injections) and was sterile on culture. C.S.F. purulent; pressure 120 mm. H_2O; protein 600 mg. per 100 ml.; culture grew *H. influenzæ* (1), growth inhibited on Fildes's agar containing 2 units of streptomycin per ml. Hæmoglobin 58%, white cells 23,000 per c.mm. (polymorphs 48%).

Treatment.—Streptomycin intramuscularly 500 mg. daily from March 30 to April 8, and intrathecally 25 mg. daily from March 31 to April 7. The first three injections were intraventricular, because the C.S.F. flowed with difficulty on lumbar puncture. The C.S.F.-streptomycin level had an average range of 4–8 units per ml.

Progress.—The patient had continuous pyrexia over 100°F throughout the illness, with frequent vomiting. *April 2 and 3:* ventricular C.S.F. contained many pus cells and protein 1500 mg. per 100 ml.; culture proved sterile. *April 9:* gastro-enteritis. *April 12:* bilateral mastoid antrotomy; no pus found; swabs sterile. *April 14:* convulsion. *April 20:* passed a formed stool and seemed to be improving, but in the evening had a convulsion, with clonic movements and spasticity of the right side. *April 21:* grey and critically ill; right-sided fits continued; an operation was performed to exclude localised intracranial pus, and no pus was found; C.S.F. contained 25 cells per c.mm., and protein 50 mg. per 100 ml.; culture proved sterile. *April 22:* the patient died.

Necropsy Findings.—Fibrous matting of leptomeninges at the base of the brain; a ragged cavity 2 cm. in diameter in the left frontal lobe, containing fragments of blood-clot, lined by soft ragged sloughing tissue and communicating with the left lateral ventricle: moderate dilatation of all ventricles; extremely fatty liver. Microscopically there was no evidence of active meningitis over the brain or cord, and no inflammatory reaction in the wall of the cavity in the left frontal lobe.

This was a moderately severe case which was by streptomycin but subsequently developed enteritis. The cause of the cavity in the frontal remains obscure. A possible explanation is that streptomycin was injected at this site.

Case 2.—A boy, aged 9 months, had begun to be f on May 2, 1947, followed two days later by a fit, with of the right side of the body, staring eyes, and and retraction of the tongue. Subsequently, whenever child cried, his right hand had twitched. On May 13 been admitted to hospital, with temperature 104°F, rate 140, respirations 36 per min., and neck rigidity fontanelle had not been tense. C.S.F. had been purulent tained gram-negative organisms resembling *H. influenzæ.* patient had been given 'Sulphamezathine' from May 11 a total of 24 g.; and penicillin 25,000 units intrathecally from May 16 to 26; 50,000 units intrathecally on al days from May 26 to June 2; and 6000 units by three-hourly from May 14 to June 2. During this there had been a persistent fever and steady de in his clinical condition. On May 31, *H. influenzæ* had been present in the C.S.F., and on June 2 the patient transferred to the London Hospital.

On Admission.—Temperature 101°F, pulse-rate 140, well-marked head retraction and opisthotonos; clenched over thumbs; legs hyperextended. The appeared mentally impaired. The fundi showed pallor of both discs. The fontanelle was not tense rigidity and generalised spasticity, with tremor of the and ankle clonus, were present. The abdominal refle absent, and all tendon-reflexes exaggerated. W count 17,000 per c.mm. (polymorphs 70%). C.S.F.: p 150 mm. H_2O; 345 cells per c.mm.; protein 110 mg sugar 35 mg. per 100 ml.; culture sterile. Blood also proved sterile.

Treatment.—Streptomycin 600 mg. intramuscularly and 100 mg. intrathecally daily from June 2 to 8.

Progress.—The patient was afebrile after three C.S.F. (June 8) 120 cells per c.mm. and protein 100 mg. 100 ml.; it subsequently became normal. level in C.S.F. 32–64 units per ml. There was no ment in the neurological condition, though general was satisfactory, and when discharged (Aug. 8, 1947) patient was mentally defective, blind with optic and had generalised spasticity. On Aug. 8, 1948, the was still alive, and his condition unchanged.

This was a subacute case deteriorating wh penicillin and sulphamezathine, though the may have been controlled. The C.S.F. was sterile on when streptomycin therapy was begun.

Case 3.—A girl, aged 9 months, had fallen from perambulator on April 1, 1947, but had not lost On April 21 she had been feverish, vomited repeatedly, been admitted to hospital with neck rigidity and C.S.F., which grew *H. influenzæ* on culture. She had given sulphonamides 3 g. daily for nine days, and p 20,000 units intramuscularly four-hourly for four days 10,000 units intrathecally once. On May 8 her cond had remained unchanged, and her C.S.F. contained 300 per c.mm. and protein 100 mg. per 100 ml. and *H. influenzæ* on culture. On May 13 the patient transferred to the London Hospital.

On admission the patient appeared pale and moderately with head retracted and neck rigid, temperature 10 pulse-rate 180 per min., right pupil dilated with no re to light. A blood-culture was contaminated. Whi count 12,200 per c.mm. (polymorphs 84%) C.S.F. cont 650 cells per c.mm., protein 140 mg. and sugar 30 mg 100 ml., and on culture grew *H. influenzæ* (3), sensiti a ring 21 mm. in diameter.

Treatment.—Streptomycin 480 mg. intramuscularly from May 13 to June 9, 50 mg. intrathecally daily from M May 13 to 15, and 25 mg. intrathecally daily from M to 26; penicillin 120,000 units intramuscularly daily May 22 to June 15, 5000 units intrathecally daily May 22 to 26; sulphamezathine 3 g. daily from Ma to June 15. The C.S.F.-streptomycin level was 10–32 per ml.

Progress.—The patient became afebrile on May 15 clinically improved by May 21. May 26: C.S.F. cont 8000 red cells and 140 white cells per c.mm., and p u—*H. influenzæ* MENINGITIS INSENSITIVE TO INCREAS- DOSES OF STREPTOMYCIN BUT RESPONDING TO COM- D THERAPY (CASE 9).

sitive to 1 unit but grew in $^1/_2$ unit streptomycin per ml.
ensitive to 400 units streptomycin per ml.

lly. On May 25 he developed measles, and on May 27 ative laryngitis for which he underwent tracheotomy; died the same day. The C.S.F. had been sterile for ays before death.

opsy Findings.—Many small patches of fibrinopurulent te on the cerebral hemispheres produced, on culture, *fluenzæ* insensitive to streptomycin. A very recent ortem thrombus in the superior longitudinal sinus. us in ethmoid air-cells, nasal cavity, and maxillary Greyish-yellow mucopurulent membrane lining the above the true vocal cords excluding the epiglottis, ring on culture *Staph. pyogenes* and *Bact. coli.* Mottled ed areas of pneumonia throughout the lungs. No mality in the right knee-joint.

is was a case of severe infection, with multiple itis. The infecting organism became rapidly sitive to streptomycin despite big doses. Increas- large intrathecal doses were used when the C.S.F.- tomycin level (repeatedly estimated) remained low. illin and sulphonamides subsequently sterilised the , but death followed measles with suppurative igitis. Necropsy showed that pus on the cerebral spheres still contained *H. influenzæ.*

se 10.—A boy, aged 1 year 11 months, had had fever anorexia on Jan. 2, 1948, and pneumonia had been osed. He had been admitted to hospital on Jan. 4, neck rigidity. His C.S.F. had contained 1000 cells per , protein 40 mg. and sugar 60 mg. per 100 ml., and, lture, had grown *H. influenzæ.* The patient had been sulphadiazine to a total of 7·5 g. and penicillin 60,000 intramuscularly four-hourly until he was transferred to London Hospital on Jan. 6.

Admission.—Temperature 100°F, pulse-rate 130 and ations 24 per min. The patient was drowsy but con- s, with well-marked neck rigidity. A blood-culture *H. influenzæ.* The C.S.F. contained 334 cells per c.mm. protein 100 mg. per 100 ml. Culture proved sterile.

eatment.—Streptomycin 600 mg. intramuscularly daily 50 mg. intrathecally daily from Jan. 6 to 15. The -streptomycin level was 8–16 units per ml.

ogress.—There was steady improvement to complete very. By Jan. 13 there was no neck rigidity and the ent was afebrile. On Jan. 15 the C.S.F. contained 48 cells c.mm. and protein 80 mg. per 100 ml. At follow-up in ust he was normal.

his was a mild case, in which the C.S.F. was sterile r penicillin and sulphadiazine, but blood-culture was positive before streptomycin treatment.

Case 11.—A boy, aged 2 years, had vomited several times and become feverish and weak on his legs on May 4, 1948. Next day he had been admitted to hospital with temperature 101°F, pulse-rate 120 and respirations 25 per min., and looking pale, ill, and slightly cyanosed, with doubtful signs in the chest and doubtful neck rigidity. Bronchopneumonia had been diagnosed and treated with penicillin 20,000 units three-hourly and sulphamezathine 0·5 g. six-hourly. Temperature had fallen during the first five days but risen again on May 10 within a day of stopping treatment. On May 17 lumbar puncture had produced C.S.F. under pressure of 300 mm. H_2O, containing 1000 cells per c.mm. and protein 45 mg. per 100 ml. Penicillin 10,000 units intrathecally daily and 20,000 units three-hourly intramuscularly had been given for three days without improvement. On May 23 the infecting organism had been identified as *H. influenzæ.* On May 24 the patient was transferred to the London Hospital.

On Admission.—Temperature 100°F. Moderate neck rigidity. Blood-culture grew *H. influenzæ.* White-cell count 25,000 per c.mm. (polymorphs 75%). C.S.F. contained 960 cells per c.mm., protein 60 mg. and sugar 57 mg. per 100 ml., and on culture grew *H. influenzæ* (1), sensitive to a ring 22 mm. in diameter.

Treatment.—Streptomycin 500 mg. intramuscularly and 50 mg. intrathecally daily from May 24 to June 2. The C.S.F.-streptomycin level was 8–16 units per ml.

Progress.—On May 26 the patient became afebrile and began a rapid clinical improvement (fig. 2). On May 28 there was no neck rigidity, and he was playing. On June 1 the C.S.F. contained 12 cells per c.mm., protein 50 mg. and sugar 51 mg. per 100 ml. On June 5 the patient's temperature was 101°F, and he was fretful and crying, with watery nasal discharge, injected fauces, and neck rigidity. The C.S.F. contained 610 cells per c.mm., protein 200 mg. per 100 ml., and on culture grew *H. influenzæ* (1).

Further Treatment.—Streptomycin 500 mg. intramuscularly daily from June 5 to 17, and 50 mg. intrathecally from June 5 to 14. The C.S.F.-streptomycin level was 16 units per ml.

Further Progress.—Clinical improvement was noted on June 9, on June 12 there was no neck rigidity, and on June 13 the patient was afebrile. He made an uneventful recovery (see fig. 2), and at follow-up in August he was normal.

This was a moderately severe case which relapsed after apparent recovery and was cured by a second course of streptomycin.

Case 12.—A boy, aged 2 years 9 months, had developed anorexia, vomiting, increasing restlessness, and drowsiness on April 5, 1947, and frontal headache on April 7. At 10 P.M. on April 8 he was admitted to the London Hospital.

On Admission.—Temperature 102°F, pulse-rate 160 and respirations 22 per min. The patient was very ill and faintly cyanosed, lying with his eyes half-closed and head retracted. His fauces were injected. No abnormality was detected in the respiratory system. He was semicomatose, reacting to pin-prick but not to spoken commands. Neck rigidity was severe; flexion caused piercing screams. There was generalised hypotonia, with abdominal reflexes absent. The left plantar response was flexor, and the right extensor. Blood-

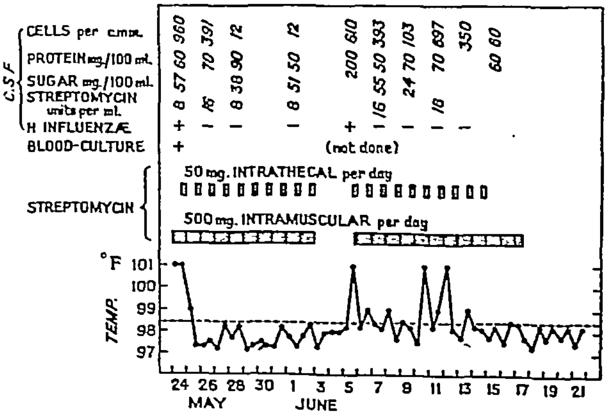

Fig. 2—Chart of mild case, showing apparently satisfactory response to streptomycin followed by relapse (case 11).

left base, and the patient was given sulphadiazine 1·5 g. daily for six days in view of the possible development of pneumonia. The C.S.F. contained 52 cells per c.mm., protein 40 mg. and sugar 50 mg. per 100 ml., and on culture proved sterile. On May 14 there was a sudden rise in temperature, and the C.S.F. contained 295 cells per c.mm., protein 40 mg., and sugar 30 mg. per 100 ml., and culture gave *H. influenzæ* (1). Blood-culture was sterile.

Further Treatment.—Streptomycin 500 mg. intramuscularly daily and 50 mg. intrathecally daily from May 13 to 19. The C.S.F.-streptomycin level was 8 units per ml.

Further Progress.—Some improvement followed. The patient was smiling and taking more interest. On May 19 there was no neck rigidity and no pyrexia. On May 21 there was pyrexia in the evening, and the C.S.F. contained 37 cells per c.mm., and protein 35 mg. per 100 ml., but culture proved sterile. On May 22 the C.S.F. contained 19,000 cells per c.mm., protein 120 mg. and sugar 32 mg. per 100 ml., and on culture produced *H. influenzæ* (3), sensitive to a ring 15 mm. in diameter. Blood-culture also proved positive.

Further Treatment.—Streptomycin 500 mg. intramuscularly daily from May 22 to June 2, and 50 mg. intrathecally daily from May 22 to June 1. On May 22 specific type-B *H. influenzæ* rabbit antiserum 50,000 units was given intravenously.

Further Progress.—Bilateral myringotomy was done on May 28, but no pus was found. On May 31 the patient was pulling herself up and playing. Lumbar puncture became increasingly difficult. The C.S.F. tended to be bloodstained and showed a rise in protein content to 200 mg. per 100 ml. on May 29. The possibility of a spinal block developing was considered, but in view of her clinical improvement it was decided to treat her conservatively, and streptomycin was discontinued. On June 3 the patient had an urticarial eruption; otherwise recovery was uneventful (see fig. 1), and at follow-up in August, she was normal.

This patient was severely ill, with drowsiness and protracted semicoma suggesting encephalitis. She relapsed twice after two full courses of streptomycin, but recovered after a third course combined with type-B *H. influenzæ* antiserum.

Case 8.—A boy, aged 16 months, whose sister had died in 1937 of *H. influenzæ* meningitis at the age of 13 months, had been visited on Dec. 13, 1947, in a day nursery by his father, who had noted that he was thin and pale, "had a vacant look," and gave no sign of recognition. On Dec. 17 the child had been admitted to hospital with neck rigidity. A lumbar puncture had produced turbid C.S.F. containing gram-negative bacilli, but sterile on culture. He had given sulphamezathine 4 g. and sulphadiazine 1·5 g. Dec. 18 he was transferred to the London Hospital.

On Admission.—Temperature 101°F, pulse-rate 138 respirations 36 per min. The patient lay quietly but easily roused. Neck rigidity was present. There was swelling of the right arm, which showed an increase of 1 in circumference around the elbow. Hb 71%, whi count 17,600 per c.mm. (polymorphs 57%). C.S.F. cont 12,700 cells per c.mm., and protein 40 mg. per 10 and on culture gave *H. influenzæ* (1).

Treatment.—Streptomycin 500 mg. intramuscularly and 50 mg. intrathecally daily from Dec. 19 to 27 C.S.F.-streptomycin level was 2–8 units per ml.

Progress.—On Dec. 22 there was clinical improvement no neck rigidity. On Dec. 23 the patient was af On Dec. 27 his right arm was no longer swollen, and C.S.F. contained 60 cells per c.mm. and protein 50 mg. 100 ml. At a follow-up in August, 1948, the patient very well, except that he seemed slightly deaf. He had yet begun to talk.

This was a mild case, with arthritis of the right el which responded well to streptomycin.

Case 9.—A boy, aged 17 months, had frequent at of projectile vomiting and became listless on April 1947. Next day he was semiconcious and was taken to h where lumbar puncture had produced turbid C.S.F. w on culture grew *H. influenzæ*. On April 26 the patient transferred to the London Hospital.

On Admission.—Temperature 102°F, pulse-rate 1 respirations 32 per min. The patient was drowsy, ill grey, but coöperative. The spleen was palpable. was moderate neck rigidity. A blood-culture was po Hb 65%, white-cell count 19,000 per c.mm. (polym 48%). C.S.F. contained 6000 cells per c.mm. and p 120 mg. per 100 ml., and on culture grew *H. influenzæ*.

Treatment.—Streptomycin 400 mg. intramuscularly from April 26 to 28, 840 mg. intramuscularly daily April 29 to May 5, and 75–200 mg. intrathecally daily April 26 to May 1; penicillin 50,000 units intramus four-hourly from April 30 to May 14; and sulphame 4·5 g. daily from May 2 to 5, and 3 g. daily from to 14 (see table II).

Progress.—On April 28 the intrathecal dosage of s mycin was increased because the C.S.F.-streptomycin remained low. On April 29 the patient was found to arthritis involving the right knee, right elbow, left and the interphalangeal joints of both big toes; 20 pus was aspirated from the knee, and on culture it *influenzæ*. Streptomycin 25 mg. was in into the knee-joint and into the left The legs were immobilised in extension April 30, because *H. influenzæ* was still cultured from the C.S.F., intramu penicillin therapy was started. On May patient was deteriorating, and intrat streptomycin was discontinued because infecting organism had become re Sulphamezathine therapy was started. May 10 the patient was much impro playing with toys, but still febrile. Pus the knee was sterile. On May 14, the c having been sterile for twelve days and taining 3 cells per c.mm. and protein 20 per 100 ml., chemotherapy was stopped. May 16 the patient had a relapse, vomiting and fretfulness, but no definite rigidity. A blood-culture was positive C.S.F. contained 3000 cells per c.mm. protein 50 mg. per 100 ml., and on cul grew *H. influenzæ* (2) insensitive to str mycin but slightly sensitive to penicillin.

Further Treatment.—Sulphamezathine daily; penicillin 50,000 units in muscularly four-hourly from May 16 28, 10,000 units intrathecally daily for days, and 5000 units intrathecally daily eight days from May 18 to 28.

Further Progress.—On May 21 the C contained 40 cells per c.mm. and protein mg. per 100 ml. There was continuous f over 100°F, but the patient began to imp

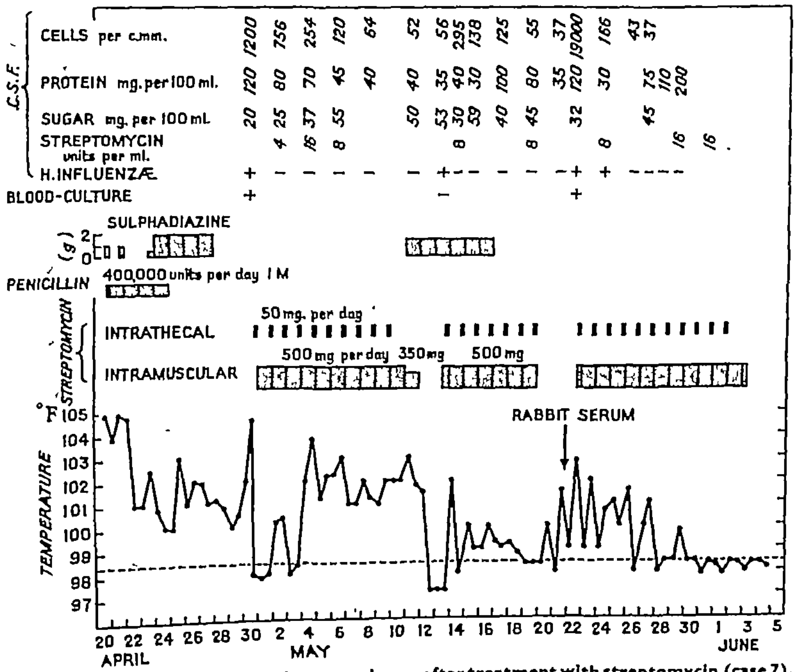

Fig. 1—Chart of severe case, showing two relapses after treatment with streptomycin (case 7).

ılphonamides. Subsequently there was a relapse
was controlled by the same treatment. Death
ue to a complicating suppurative laryngitis when
s.F. had been sterile for nine days, and there was
l evidence of improvement of the meningitis.
psy showed scattered areas of pus over the cerebral
heres from which *H. influenzæ* was grown. Such
ight well be responsible for relapses. Presumably
er cases such residual foci may be situated in the
joints, middle ears, or sinuses, and may be the
of a relapse with septicæmia and meningitis.
ps more attention should be directed to the
s, which may be involved in the initial infection
upper respiratory tract. Field and Rogers (1936)
ed a case of meningitis which they considered
lary to an infected sphenoidal sinus from which
fluenzæ was grown post mortem. Mucopus was
in the maxillary and ethmoid antra at necropsy
e 9; unfortunately it was not cultured. Presumably
nger these foci have been present the longer they
o resolve. This may explain why relapses occurred
es of relatively long duration before streptomycin
nent was started.

herefore appears that it is justifiable to discontinue
omycin when the C.S.F. has been sterile for at least
k in early moderately severe cases. Treatment
have to be prolonged, however, if the temperature
rsistently raised, if there has been a long illness
e the infection is controlled, if there is an active
of infection, or if the response to treatment is slow.
ly long courses of streptomycin may be avoided
mbining it with sulphonamides. Both drugs could
ed in the acute stage, after which a further course
ılphonamides may prove adequate in preventing
pse.

tomycin Resistance

exander (1947) has shown that the development of
istant strain of *H. influenzæ* is due to the elimination
ll sensitive organisms and to the survival of the
few insensitive forms that occur in every large
erial population. A few resistant organisms can be
n from nearly every case, but it is only in very
te infections that they succeed in establishing
selves. If this happens it usually follows shortly
the start of streptomycin therapy. Case 9 is an
nple of this type, the organism becoming resistant
orty-eight hours. There is no reason to suppose
dosage was inadequate, but it was remarkable that
C.S.F.-streptomycin levels remained persistently low
ite big intrathecal doses. No resistant strains
loped from any of the cases that relapsed. A sensi-
strain was grown from case 7 after nineteen days'
ptomycin therapy.

ombined therapy therefore seems to be indicated in
re infections, because a single chemotherapeutic
nt may destroy a large proportion of the organisms
leave sufficient numbers to maintain the infection.
second drug, less effective by itself, may play a
sive part by destroying these remaining organisms.
s is of paramount importance in severe *H. influenzæ*
ction, since there are no indications of when a resistant
in may emerge. Theoretically, combined therapy with
ptomycin, rabbit antiserum, and sulphonamides should
ve most effective if given at the onset, when the
nber of streptomycin-resistant organisms is still small.
abbit antiserum is not obtainable, a combination of
ptomycin, penicillin, and sulphonamides may prove
be the treatment of choice.

SUMMARY

treptomycin was given in 12 cases of *H. influenzæ*
ningitis. One case is excluded because there was no
teriological evidence of active infection on admission.
Of the remaining 11 patients 3 died, and in 1 of these the organism became resistant to streptomycin.

The clinical picture is described with a view to earlier diagnosis and the recognition of severe cases.

Streptomycin gave good results in the mild or moderately severe cases but was unsatisfactory in 3 severe cases.

In 3 cases a relapse followed a full course of streptomycin. Factors that might predispose to a relapse are discussed, with particular reference to the duration of treatment.

In view of the failure of streptomycin in severe cases and of the possible development of resistant strains, it is recommended that all cases should be treated with streptomycin and sulphonamides. If there is any reason to suspect a severe infection, either antiserum or penicillin should be given in addition.

I wish to thank Dr. K. H. Tallerman, M.C., and Dr. R. H. Dobbs for permission to publish these cases; Prof. Clifford Wilson and Dr. F. C. O. Valentine for their valuable advice and guidance, and the latter also for the bacteriological investigations: and Dr. H. G. Dunn for his help and criticism.

AN ARTIFICIAL HEART OR CARDIOPULMONARY MACHINE

PERFORMANCE IN ANIMALS

VIKING OLOV BJÖRK
M.D.

From the Surgical Clinic of Sabbatsberg Hospital, Stockholm, Sweden

IN experimental and clinical work which he began in 1935 Crafoord found it possible to suspend the flow of blood to all organs but the brain for a considerable time without damaging them. Thus, in 33 patients undergoing operation for patent ductus arteriosus he double-clamped the aorta for 10–27 min.—in most cases more than 20 min.—just below the point where the left subclavian artery arises, without causing any subsequent disturbances in the patients' internal organs.

In view of this experience Crafoord thought it possible to achieve a bloodless approach to the inside of the heart, arresting the circulation of blood but maintaining an adequate flow through the brain with a cardiopulmonary machine. In 1946 Crafoord and Andersson constructed an artificial heart, which I have studied in experiments on animals.[1] Thus in a dog I have clamped both superior and inferior venæ cavæ for 33 min., rendering the heart bloodless but maintaining the blood-flow to the brain alone with the cardiopulmonary machine. The dog survived with no sign of organic damage and became father to eleven puppies.

Though all the other organs will tolerate an arrest of the circulation for half an hour, a few minutes' anoxia damages the brain. During a bloodless intracardiac culture proved sterile. The C.S.F., under a pressure of 300 mm. H_2O, contained 17,000 cells per c.mm., and grew *H. influenzæ* on culture.

---

[1] Björk, V. O. (1948) *Acta chir. scand.* suppl. 137.

Treatment and Progress.—Streptomycin $^1/_6$ g. intramuscularly four-hourly, and 50 mg. intrathecally immediately. Twelve hours later (April 9) there was an abrupt onset of choking, with bubbling noises in the pharynx; this cleared after half an hour. Temperature 104°F, pulse-rate 160 per min. The patient was critically ill, and his colour ashen grey. Signs of consolidation in the left upper lobe were confirmed by radiography. Lumbar puncture was done at 6 P.M. and streptomycin 100 mg. was given intrathecally. The C.S.F.-streptomycin level was 2 units per ml. Gram-negative coccobacilli were present in a film of C.S.F. The patient died at 11 P.M.

Necropsy Findings.—Purulent meningitis; ill-defined areas of peribronchial consolidation in the lungs; stomach contents and greenish-yellow mucus filling trachea and bronchi. In a smear from meningeal pus gram-negative organisms were seen, but a culture was contaminated. Ventricular fluid contained gram-negative organisms. Culture from the lungs gave *Staph. pyogenes.*

This was a fulminating infection with meningitis and pneumonia, and the patient died twenty-five hours after streptomycin therapy had been started.

DISCUSSION

Though probably less common in this country than in the United States (Mutch 1941), *H. influenzæ* infection is an important cause of suppurative meningitis, particularly in children under the age of 2 years. In the present series 12 cases were admitted in fifteen months. All were transferred, however, from hospitals covering a wide area. A more normal rate of admission is indicated by a review of 10 cases admitted to the London Hospital in 1927–36 (Williams and Tallerman 1937).

No attempt is made to describe the clinical picture in detail, but a few points are emphasised that may help in early diagnosis, since this is essential if good results are to be achieved.

The diagnosis is most difficult in young infants, the age at which the prognosis is worst (Alexander 1943). Not infrequently a mild upper respiratory infection precedes an abrupt febrile onset of vomiting, irritability, convulsions, or drowsiness. Physical signs may be absent in the early stages. Increased tension of the fontanelle generally appears earlier than neck rigidity. Slight disturbances of consciousness may develop, often no more than a vacant glazed look about the eyes. In the presence of any of these physical signs, or in an unexplained pyrexia associated with any of the above-mentioned symptoms, it is essential to perform lumbar puncture. The diagnosis is then confirmed or refuted, and, if an infection is present, the type of organism can be determined.

In older children headache, vomiting, and neck rigidity are generally well marked, and the diagnosis correspondingly less difficult. All variations in the severity of the disease occur, from a fulminating type, which may even present with the Waterhouse-Friderichsen syndrome (Lindsay et al. 1940), to a subacute insidious form resembling tuberculous meningitis.

In the present cases the usual high incidence of septicæmia was found, 7 out of 9 blood-cultures being positive on admission. Arthritis developed in 3 out of 12 cases, in 2 involving more than one joint. In 4 cases the original diagnosis was pneumonia. It is important to realise that meningitis may be masked by a pneumonic mode of presentation. In some instances *H. influenzæ* pneumonia may actually precede (Huntington and Weiss 1936) or accompany the onset of meningitis, and meningitic signs may be attributed to "meningism." In other cases pneumonia may be simulated by the presence of rapid grunting respirations and by the deceptive fall in temperature and clinical improvement that may follow treatment with sulphonamides. It is unjustifiable to maintain this diagnosis in the continued physical signs in the chest or of radiographic unless meningitis has been excluded by lumbar

Some assessment of the severity of a case is re as a guide in treatment. Two types of severe occur, one a short fulminating illness, the subacute form that has deteriorated into a critic Generally the following features (largely derived Alexander's work) indicate that the disease is run a severe course.

(1) An age of less than seven months.

(2) A rapid downhill course, with the early app coma or of multiple fits.

(3) Deep and protracted coma suggesting encephalitis.

(4) Complications, especially laryngotracheo- pneumonia, or multiple suppurative arthritis.

(5) Lack of response to treatment, shown by a pers high temperature, no clinical improvement, the pers organisms in the C.S.F., or the development of re to the drug.

It has also been stated (Alexander 1944) that a sugar level of less than 15 mg. per 100 ml. ind severe infection. The sugar concentration was c in 6 of these cases, including 2 clinically severe and it exceeded this level in all of them.

Alexander et al. (1946) have stated that, streptomycin is effective in controlling mild or severe cases, it often fails in the more severe In the present small series our results point to conclusion.

Of 3 cases classified as severe on clinical one ran a rapid downhill course, the second d multiple pyarthroses and a resistant strain of and the third ran a continuous fever and a semicomatose state for nine days and su relapsed twice. All these children looked ill and dusky grey complexion in contrast to the milder who generally looked fairly well. Of the 7 mo severe cases 6 completely recovered. The one child died also had gastro-enteritis and at necropsy no evidence of active disease.

Streptomycin compares favourably with co treatment with specific antiserum and neither form of therapy alone gives satisfactory severe cases. For these Alexander et. al (1946) that treatment with all three agents would prove effective and the treatment of choice. Though combined with sulphonamides does not appear so effective as streptomycin it may yet prove combined therapy.

Relapses

In 3 cases there was a relapse after streptom treatment, 1 of these had two relapses. Such a proportion of relapses has not previously been rep with streptomycin. The initial course of treatment eight days in 1 case and ten days in the other 2, a second course of eight days was given to the case relapsed twice. The C.S.F. became sterile within four hours in each case. No definite indications of likelihood of a relapse were found, except that it more liable to occur in severe infections and fever persisted. Case 11, however, relapsed after afebrile for ten days; he had been sitting up and pl and the C.S.F. had returned almost to normal. significant feature in these cases was the duratio illness before streptomycin therapy was started. It wa fifteen, and twenty days, whereas in those that re on a single course it was four, five, eight, and ten days Alexander's 12 patients, most of whom received a shor course of treatment without a relapse, none had been longer than seven days (Alexander et al. 1946).

The necropsy in case 9 indicated a possible source a relapse. The infecting organism in this case resistant to streptomycin but responded to penic oss of water in the oxygenator was compensated by ing fluid to the blood with a drip feed during the usion. The disadvantages of hæmolysis, which some- s persisted despite every precaution, were diminished ising pure oxygen in the oxygenator, sodium bicarbo- solution being added to the blood by a drip feed nake the animal's urine alkaline. The unavoidable lolysis in the perfusion apparatus was well within limits of what can be tolerated in brain-perfusion riments. There was also some destruction of leuco- s, the lymphocytes being more resistant to mechani- trauma than the granulocytes. The thrombocytes not significantly affected.

here was a considerable fall in blood-sugar during circulation of blood in the perfusion apparatus. e the anoxic brain is especially sensitive to hypo- æmia, glucose solution was added by means of a feed.

the experiments on animals the perfusion apparatus first filled with blood taken from donor dogs and red through a 'Monell' filter (mesh 150 × 150 μ). blood in the apparatus was mixed with the dog's blood and filtered through the dog's own lungs re brain perfusion was begun. The technique was ollows. The blood from the apparatus was pumped ugh the right external jugular vein into the superior a cava and after traversing the lungs was withdrawn n one of the common carotid arteries. Thus, when n perfusion started the perfusion apparatus contained dog's own blood, mixed with donor blood which had n filtered through the perfused dog's lungs. During perfusion continuous filtration through a filter of h 300 × 300 μ was used, as a guarantee against bolism.

he apparatus has been tested in animals and found able of completely maintaining the circulation through brain for a sufficient time to permit bloodless intra- diac operations. In three dogs the vertebral arteries l veins on both sides were divided at the first stage a two-stage operation. After about 10 days the brain s perfused through the left common carotid artery, right being clamped for 25, 63, and 93 min. The ous cannula was inserted into the superior vena cava ough the right external jugular vein. After the brain l been perfused, nothing abnormal could be detected ring 5–7 months' observation.

With both the superior and the inferior venæ cavæ cluded and the azygos vein ligated, the brain was rfused for 33 min. with no ill effects on the dog. Seven gs have survived perfusion of the brain with the rdiopulmonary machine.

SUMMARY

Animal experiments have proved that the perfusion paratus described can perform the functions of heart d lungs for a sufficient time to permit bloodless tracardiac operations. Dogs have shown no ill effects fter half an hours' perfusion of the brain.

"... One finds most of the defenders of 'family integrity' the wealthier groups of society at the moment and it is t difficult to discern that, in many instances, the members those wealthier groups do, at their own expense, precisely hat they condemn in the other groups for whom the mmunity makes the corresponding provision. If it is ght to employ a 'nanny,' it is right to send a child to a ursery. If it is right to dine at the Savoy, it is right to dine a British Restaurant. If it is right to call in Sir X. Y. om Harley Street to look at a child who ails little or nothing, is right to take a child to a welfare clinic. All that remains the argument against State or community help for the mily is that nobody should receive what he cannot pay for t of his own pocket. In other words, the objection is to pauperisation' as it used to be called, which is a matter very fferent from the 'disintegration of the family.'"—*Medical ress*, Sept. 15, 1948, p. 193.

ABSORPTION AND EXCRETION STUDIES WITH RADIOACTIVE PENICILLIN

St. Mary's Hospital Medical School, London

WHEN penicillin is given parenterally it is rapidly excreted and a variable amount, up to 70%, is found unchanged in the urine (Topley and Wilson 1945). It is not known what happens to the remainder, and the weight of material involved is so small as to make this problem practically insoluble by ordinary chemical methods. Recently, penicillin containing the radioactive sulphur isotope, S^{35}, has been prepared (Rowley et al. 1948), and with this material the fate of the penicillin molecule can be followed by methods independent of biological activity.

The first experiments were designed to determine the excretion path of penicillin after intramuscular injection; then, with this information, to probe the more difficult problem of excretion of penicillin given by mouth.

For our experiments female cats were chosen, since they can easily be catheterised and produce a workable volume of urine. Premedication was given in the form of intraperitoneal urethane, 0·5 g. per kg. of body-weight, which sufficed to keep the cats docile. Immediately after the injection of penicillin the bladder was emptied with a glass catheter, the sample being discarded. Thereafter the cats were catheterised at intervals of 1 or 2 hours for 8–10 hours, the whole procedure being carried out as aseptically as possible.

Assay of Radioactivity

The radioactive penicillin used was labelled with sufficient S^{35} to enable the accurate detection of about $^1/_{10}$ unit with a Geiger counter (1 unit of penicillin was equivalent to 1100 disintegrations per min.).

The radioactivity of the samples was measured with a Geiger-Muller counter and scale-of-a-hundred recording circuit.

TABLE I—URINARY EXCRETION OF INTRAMUSCULAR PENICILLIN

operation it is therefore necessary to maintain an adequate circulation of oxygenated blood through the brain with a perfusion apparatus capable of performing the work of both the heart and the lungs. In this cardiopulmonary machine the saturation with oxygen of a rapidly moving blood-stream must be achieved with the lowest possible destruction of red cells. At the same time physicochemical changes in the blood must be kept within normal limits.

THE APPARATUS

The main principle of the artificial blood-oxygenator is the brief exposure to oxygen of films of blood of as large an area as possible—i.e., the total area of blood film exposed per minute must be very large. In the apparatus we devised the blood flows through a trough occupying the lower part of a horizontal cylinder. This trough is divided into sections by partitions so made that the blood, passing from one section to the next, flows alternately over and under successive partitions (fig. 1). Through the cylinder runs a central axle bearing 40-50 discs in groups of 4 which dip into the blood and, as they rotate, expose new films of blood to the oxygen in the cylinder. This arrangement facilitates the mixing of oxygenated and unoxygenated blood. It also prevents some of the blood from remaining at the bottom of the trough throughout its passage through the cylinder. The upper part of the cylinder consists of a detachable tight-fitting lid of 'Plexiglass,' which allows the blood to be inspected at any time. The discs are of rhodium-plated stainless steel, 0·5 mm. thick, 13 cm. in diameter, and 4 mm. apart (closer discs were found to cause foaming). The axle is rotated at about 120 r.p.m. by a 40-watt electric motor.

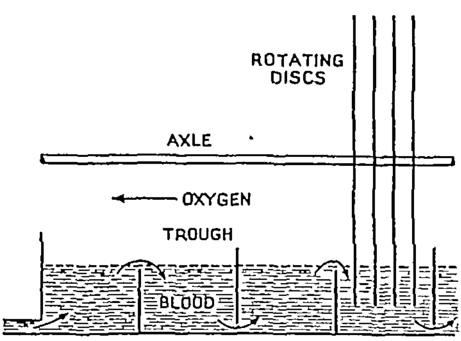

Fig. 1—Scheme of circulation through the oxygenating cylinder.

The pump (fig. 2) consists of a metal cylinder with a rubber cuff on the inside. The rubber tube for the blood passes through the centre of this cuff between two valves, made of a thin rubber band on a metal frame. The pumping action is attained by rhythmically inflating the cuff with compressed air, so squeezing the rubber tube.

The perfusion apparatus is shown in fig. 3, in which tube 1 conveys venous blood from the animal to a 20 ml. glass cylinder (2) and the rate of blood-flow can be determined by measuring the time taken by the blood to fill the cylinder when the tube to the oxygenator is closed and an air outlet is opened. From this cylinder the blood enters the oxygenator (3). Oxygen is supplied through a flow-meter; it is warmed in a metal tube passing over two 150-watt bulbs and travels in the opposite direction to the blood. There are two outlets for blood from the oxygenator. One (4) leads into a glass tube in front of a photo-electric cell, which keeps the blood in the oxygenator at about the same level by regulating the speed of the pumps. This blood re-enters the main blood-stream at 5, so that there is a continuous circulation of blood in these side tubes; otherwise the sedimentation of red cells would produce a translucent layer of plasma at the top of the blood in front of the photo-electric cell, which would then act incorrectly.

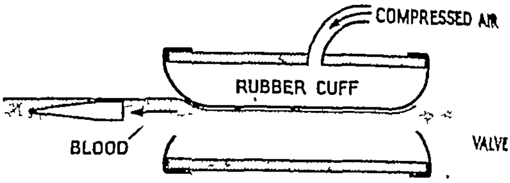

Fig. 2—Diagram of pump.

The saturated blood leaves the oxygenator tube 6, which divides into two parallel tubes, through the pumps (7), which work in parallel alternate pulsations. The two blood-streams ne bine and pass through a filter. Subsequently the passes between the walls of a double-walled glass containing the contact thermometer, the in the cup being filled with oil. There is a branch to a manometer (9) for blood-pressure reading. entering the artery through tube 10, the blood through a glass vessel, where any small air-bubble removed.

Latex surgical rubber tubing, with glass conne used. All glassware, rubber tubing, valves, and trough are coated with silicon to give them a and water-repellent surface. A solution of $(CH_3)_2Si($ and $CH_3Si(OH)_3$ in the proportion of 9:1 ('Si UHB 300,' Swedish patent 3408/48) is used.

RESULTS

The rate of gas-flow through the oxygenator was to have no significant effect on oxygenation or on elimination of carbon dioxide. Experiments with mixtures of oxygen, nitrogen, and carbon dioxide that an increase in the partial pressure of oxygen in oxygenator improved oxygenation but had no effect the elimination of carbon dioxide, which depended the partial pressure of carbon dioxide in the gas Raising the temperature improved both oxygenation the elimination of carbon dioxide. The optimal of exposure of each blood film to oxygen in the genator was found to be 0·4–0·5 sec. An increase n number of rotating discs increased the oxygenation

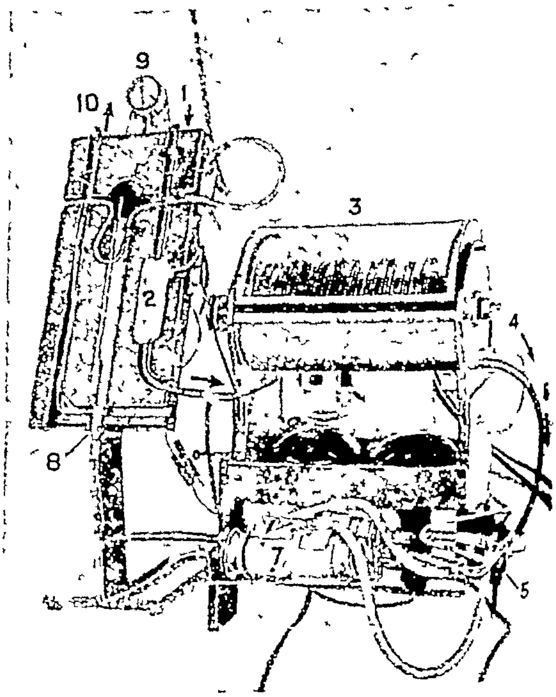

Fig. 3—The cardiopulmonary machine.

kdown products. Stewart and May (1947) concluded "The most important factor influencing the absorp- of penicillin [given by mouth] seems to be the plained individual variations in the absorptive city of the gut." From the present work it seems once the penicillin has crossed the intestinal wall ehaves in a manner exactly similar to injected cillin. It has been shown that the scanty excretion of cillin given by mouth can largely be explained by mplete absorption. Further studies directed towards oving absorption from the gut therefore seem to be h while.

SUMMARY

rinary excretion studies were carried out in female using penicillin labelled with S^{35}.

tramuscular injections of ordinary and labelled cillin gave rise to a urinary excretion of 100% of the oactive sulphur isotope, but to a much smaller very of penicillin.

here was no evidence of retention of penicillin in body as the radioactive breakdown products were eted over the same time interval as the penicillin.

hen the labelled penicillin was given by mouth much was excreted; the amount of radioactivity remaining he gut at the end of the experiment suggested that -absorption would account for the penicillin not d in the urine.

e wish to thank Sir Alexander Fleming for his continued rest in the work; the Medical Research Council for the rous gift of S^{35}; E. Lester Smith, D.SC., for the prepara- of the radioactive penicillin; Messrs. P. Roberts, B.SC., P. D. Cooper, B.SC., for valuable assistance; and the mmond Research Fund (D.R.) and the Sir Halley Stewart t (H.C.S.) for their continued financial support.

INTESTINAL OBSTRUCTION DUE TO ASCARIASIS

REPORT OF A CASE

KHALID NAJI
B.M., M.S.
SIDENT SURGICAL OFFICER, TEACHING HOSPITAL, BAGDAD

A BOY, aged 14, a labourer, was admitted to this spital with thirty-six hours' history of abdominal lic, which had increased in intensity for twenty-four ours, with vomiting on six occasions and no passage f flatus or fæces in the last twenty-four hours. His st motion had been mixed with blood. For two months e had been losing weight and strength. He had reviously passed long worms in his stools and had had ttacks of colic during the last two months. After reatment by his doctor he had passed about 15 round-orms. Other members of his family had also passed undworms. The patient had no history of any other isease.

On admission the patient was anæmic, looked ill, had tacks of colic every few minutes, and vomited a roundworm, o cyanosis, no jaundice, no dyspnœa, no œdema, no clubbing fingers. Temperature over 101°F, pulse-rate 120 per min., spirations 26 per min., blood-pressure 120/80 mm. Hg. ongue furred and moist; teeth and tonsils clean and normal. bdomen moved freely on respiration; slight bulge in right pochondrium and epigastrium; peristalsis visible during lic, when a sausage-shaped mass was also seen in the igastric and both hypochondriac areas. This mass was nder on palpation and dull on percussion, rest of abdomen being soft, not tender, and resonant on percussion. Spleen not palpable; liver not enlarged. Peristaltic sounds heard on auscultation. Nothing abnormal detected per rectum except bloodstained mucus. Heart and lungs normal.

Treatment.—Two enemas produced neither flatus nor fæces. The patient was given morphine gr. $^1/_6$ and atropine gr. $^1/_{200}$ and prepared for laparotomy, intussusception having been diagnosed.

Operation.—Under general anæsthesia, induced with chloroform and continued with ether, a right paramedian incision was made, extending $2^1/_2$ in. above and below level of umbilicus. When peritoneum was incised, 2 ft. of much distended small intestine bulged out. Intestinal wall of the loop was so thin that it was transparent, revealing a compact mass of roundworms. Loop was 2 ft. proximal to ileocæcal junction; associated mesenteric lymph-glands enormously enlarged. Owing to thinness of intestinal wall and danger of rupture on manipulation I packed the peritoneal cavity; I then made a 2 in. incision in middle of loop, and evacuated 402 roundworms with sponge forceps. Loop was repaired with double layer of continuous sutures, and abdomen was closed. Operation lasted 55 min.

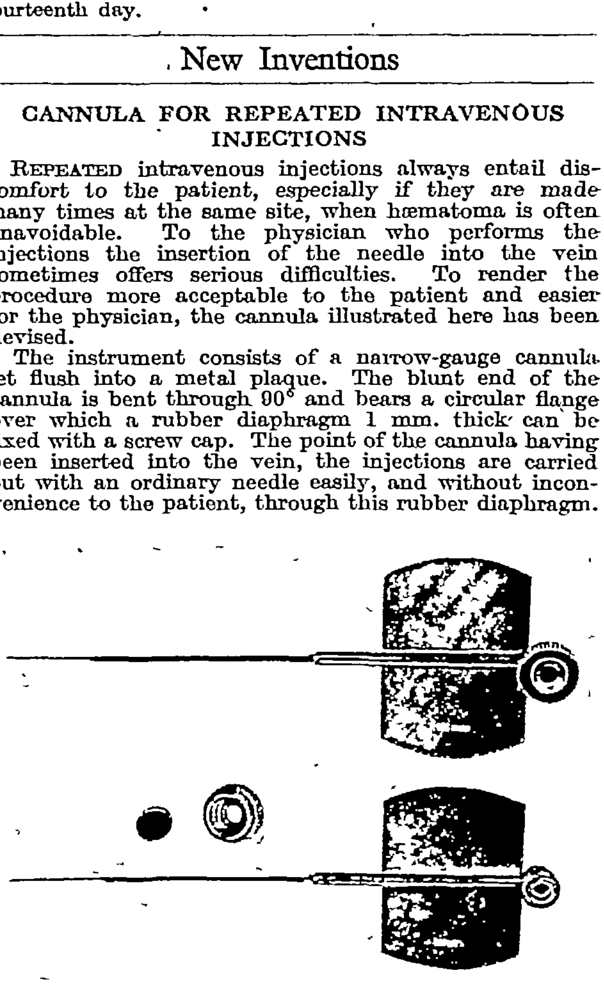
Postoperative Treatment.—To prevent ileus, the patient was given continuous rectal saline, and morphine gr. $^1/_6$ at midnight. Next day he was started on pituitary extract 0·5 ml. twice daily, and had acetylcholine 1 ml. twice. On third day rectal saline was stopped and fluid was given by mouth. On fourth day a morning enema produced fæces; temperature normal; pulse-rate 90. On fifth day pituitary extract was stopped, and the patient was given light diet and a morning enema. On seventh day the patient was given santonin gr. 6 followed by castor oil, and four roundworms were passed. Santonin gr. 3 and castor oil was given on eighth and ninth days, and on ninth day 19 roundworms were passed. Full diet was given, and stitches were removed on tenth day. The patient was discharged from hospital on fourteenth day.

New Inventions

CANNULA FOR REPEATED INTRAVENOUS INJECTIONS

REPEATED intravenous injections always entail discomfort to the patient, especially if they are made many times at the same site, when hæmatoma is often unavoidable. To the physician who performs the injections the insertion of the needle into the vein sometimes offers serious difficulties. To render the procedure more acceptable to the patient and easier for the physician, the cannula illustrated here has been devised.

The instrument consists of a narrow-gauge cannula let flush into a metal plaque. The blunt end of the cannula is bent through 90° and bears a circular flange over which a rubber diaphragm 1 mm. thick can be fixed with a screw cap. The point of the cannula having been inserted into the vein, the injections are carried out with an ordinary needle easily, and without inconvenience to the patient, through this rubber diaphragm.



S^{35}, an isotope with a half-life of 87 days, emits β rays of small penetrating power. In measuring such soft radiations difficulties are encountered owing to the absorption of the β rays both in the window of the Geiger counter and in the material of the sample (self-absorption). The former difficulty was largely overcome by using on the counter a very thin mica window through which the radiations could pass readily. To correct for self-absorption samples containing known amounts of S^{35} mixed with known amounts of absorbing material were assayed. From these results a graph was drawn relating loss from self-absorption to weight of the sample. In this way correction could be made for self-absorption in each of the samples measured. To ensure the greatest possible accuracy the procedure was designed to keep this correction as small as possible. In preparing for radioactive assay each sample was diluted to $^1/_6$ with distilled water, and 100 c.mm. was pipetted on to a nickel planchette and dried by heating at 130°C for 15 min. The planchettes were kept in a desiccator over calcium chloride until the actual counting, since they were found to absorb water vapour, so increasing the self-absorption of the material.

To minimise statistical errors, at least 5000 counts were taken with each sample, and each count was continued for more than 5 min., to give a timing error less than the statistical error. The total error in the radioactive assay of each sample was less than 5%.

Biological Assay

For our purposes the plate method (Fleming 1942) was satisfactory. As Heatley (1944) has shown, there may be an error in this method of ± 30%. Estimation was greatly facilitated in our case by our knowing from previous radioactive measurements the approximate concentration of penicillin to be expected. The amount of penicillin in the pooled samples from each cat was doubly checked by extraction with an equal volume of amyl acetate at pH 2·5 to remove 95% of the biological penicillin (Ro et al. 1946). The number of units extracted correspo exactly to the sum of the individual bio-assays. Thr this double check the error in our bio-assays is likely t be less than the figure given above.

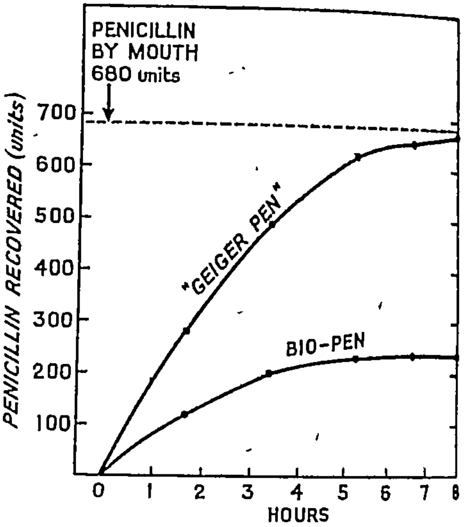
* Repeat of cat no. 7.

† Cat no. 10 was killed, and Geiger-pen units were determined in the contents of its whole gastro-intestinal tract, as follows:

		Geiger-pen (units)
Stomach	Vol. 60 ml.	166
Small gut	Vol. 80 ml.	183
Large gut	Vol. 80 ml.	0
		349



Urinary excretion of penicillin given by mouth to cat 5.

EXPERIMENTAL RESULTS

For easy comparison the radioactivity in the various urines has been back calculated into "Geiger-penicillin units" on the basis of 1100 disintegrations per min. being equivalent to 1 unit of penicillin. Some of this radioactivity was present as penicillin breakdown products; the amount of this non-penicillin radioactivity was calculated by subtracting the biological-penicillin (bio-pen) level from the "Geiger-penicillin" (Geiger-pen) level.

Intramuscular Injection.—The results of intramuscular injections of labelled penicillin are summarised in table I; the excretion curve from cat 5 is shown in the accompanying figure. It is apparent from these results that the difference between the amount of penicillin injected and that which appears as bio-pen in the urine is represented by breakdown products of penicillin excreted in the urine as rapidly as the penicillin itself.

Penicillin by Mouth.—In these experiments, solid food having been withheld for the previous 24 hours, the penicillin was given by stomach-tube and washed down with an equal volume of water. Otherwise the technique was the same as before.

The results of these experiments, summarised in table II, show that, when penicillin is given by mouth, by no means all the penicillin or its breakdown products are recovered from the urine. In cat 10 an attempt was made to determine whether this was due to retention in the intestinal lumen. Six hours after penicillin had been given by mouth the cat was killed and the radioactivity of the contents of various portions of the gut determined after thoroughly washing through the gut with water. It was found that 59% of the original radioactivity still remained in the gut, whereas 24% had appeared in the urine. In spite of the fact that urinary excretion had not finished, the presence of such a large proportion of the original activity in the gut after six hours strongly suggests that non-absorption from the gut is the reason for the low urinary excretions after penicillin has been given by mouth.

DISCUSSION

The experiments with intramuscular penicillin clearly show that it is not stored in the body at all but is quickly excreted, partly as penicillin and partly as penici

THE LANCET

LONDON: SATURDAY, SEPT. 25, 1948

Penicillin in Syphilis

VE years have passed since penicillin was first in syphilis, and it is doubtful whether its value be fully assessed for at least another five. Yet, ite of some early doubts and disappointments, s been accepted almost universally and there can o doubt that it has come to stay. In the United es a report,[1] based on the treatment of half a on cases, assesses the present position. Crystalline cillin II (G) is regarded as superior to the impure mercial product, and it is best given intramuscu- in doses of 20,000 to 100,000 units dissolved in le water or isotonic saline every two or three s day and night. The alternative is to inject a ension of calcium penicillin in arachis oil with % beeswax in a daily dose of 600,000 units. The method requires admission to hospital and the recommended for early syphilis is 4·8 million s given in 96 doses, each of 50 000 units at two- r intervals day and night for eight days. With oil- mixture the daily dose is given for ten days, the l dosage being 6 million units. With both methods, n penicillin is used alone, the failure-rate of resis- t cases and relapses is about 15% at the end of ar. The addition to this treatment of arsphenoxide n intensively in the form of 8 injections each of mg. daily or every other day, and bismuth sub- cylate in 5 doses each of 0·2 g. every two or three s, does little to diminish the failure-rate. With litional fever therapy results have been little better, this supplementary treatment adds to the diffi- ty of getting patients to coöperate.[2] Such accessory thods also involve increased risks to the patient d are therefore reserved for resistant cases, in ich they are combined with more penicillin.

For latent syphilis, in which the duration of infection often uncertain, penicillin has been used in the same sage on the assumption that it will heal undetected ions and may prevent the development of clinical anifestations later. It seems to be no more effective an arsenicals and bismuth in converting positive rum tests to negative in cases of late and latent fection, a finding which accords with the experience WILLCOX[3] in this country. Penicillin has proved effective as older remedies in healing the cutaneous, icous, osseous, and visceral lesions of so-called nign late syphilis; but with these conditions, as th latent syphilis, many years must pass before tistics can show whether it will secure a good imate prognosis. The same applies to cardio- scular syphilis, and the possibility of dangerous Herxheimer reactions remains where syphilitic aortitis is complicated by aortic regurgitation, saccular aneurysm, or involvement of the coronary ostia; in such cases penicillin, if it is used at all, should only follow protracted treatment with heavy metals. For neurosyphilis of the meningeal and vascular types a dosage of 4–10 million units is recommended, given in aqueous solution over a period of seven to twenty-one days without adjuvant treatment. For parenchymatous neurosyphilis 10–20 million units is given in twelve to twenty days, accompanied by malaria therapy unless this is contra-indicated. In neurosyphilis of all kinds intramuscular administration seems to be as effective as intrathecal and is certainly much safer. For the prevention of syphilis in the unborn child penicillin has been remarkably successful and seems to be almost fully effective at whatever stage of pregnancy it is given. Dosage varies from 4·8 to 6 million units, given in aqueous solution at intervals of two to three hours over eight to fifteen days. Additional treatment is regarded as unnecessary and undesirable. For infantile congenital syphilis penicillin in aqueous solution is given every two or three hours day and night in a total dosage of 100,000 to 400,000 units per kg. of body-weight over one to two weeks. The results are excellent and the death-rate has been no higher than with other methods, most deaths being attributable to nutritional difficulties or intercurrent disease. For the later manifestations of congenital syphilis the results with penicillin have been much the same as in late acquired syphilis, and the ultimate outcome in these cases remains equally in doubt. Like other forms of treatment penicillin is of uncertain value for interstitial keratitis.

Penicillin has the outstanding advantage that, as its toxic effects are few and not dangerous, a massive dosage can be given in a short time. Because of its safety and its prompt and satisfactory effect it may now be accepted as the remedy of choice for syphilitic pregnant women and for infants with congenital syphilis. In cases of benign tertiary syphilis the patient's immunity processes have already given him a large measure of protection, and treatment will readily restore a temporary loss of balance between infection and immunity. Here penicillin appears to have great advantages whether used alone or supplemented by other measures. The chief outstanding problem is whether we are justified in treating early syphilis with penicillin alone, for at this stage the immunity reactions are not fully developed and insufficient treatment may be worse than none. The verdict in the United States so far is in favour of penicillin alone, and it may be said that this treatment is free from danger, the proportion of successes seems reasonably high, and the short duration of treatment throws into sharp relief the small number of cases which are likely to be resistant to any form of treatment and will require special measures.

In most British clinics the practice is to supplement adequate penicillin therapy with at least one full course of arsenicals and bismuth, given in weekly doses for ten weeks or so. This prolongs treatment considerably and increases its dangers. If it can be shown that this procedure greatly reduces the incidence of failures then it is probably justified.

Syphilis Study Section, National Institute of Health, U.S. Public Health Service. *J. Amer. med. Ass.* 1948, 136, 873.

Schwemlein, G. X., Bauer, T. J., Craig, R. M., Rodriquez, J., Bundesen, H. N. *Ibid*, 137, 1209.

Willcox, R. R. *Lancet*, 1947, ii, 8.

It is advisable to remove the cap and diaphragm before inserting the point of the cannula into the vein so that escaping blood will show that the point of the cannula has entered the lumen of the vein. The cannula is kept in place with strips of tape crossing the metal plaque. The rubber diaphragm can easily be changed for a fresh one after a considerable number of injections. The cannula can be inserted at any site, but preferably into the dorsum of the hand or the forearm, and can be left there for several days.

Hitherto its most extensive use has been in heparin treatment and general intravenous anæsthesia. It has also been adopted for protracted intravenous infusion and blood-transfusion. For several years this cannula has been used extensively in the surgical departments of the Swedish hospitals. At Serafimerlasarettet in Stockholm it is used in practically all operations. All intravenous injections during operation are given with it. When it is used for infusions during operation, the person giving the infusion should steady with his hand the infusion needle through which the liquid is introduced into the cannula. After each injection the rubber diaphragm is cleaned with alcohol or ether; the cannula may also be protected with sterile surgical gauze. The cannula is used daily in our operation services and, so far as I know, there has never been a case in which septicæmia could be attributed to it.

Stockholm. THORE G. OLOVSON, M.D.

Reviews of Books

Lecture Notes on Pharmacology

J. H. BURN, M.D., F.R.S., professor of pharmacology, University of Oxford. Oxford: Blackwell Scientific Publications. 1948. Pp. 128. 6s.

IT may be doubted whether many students, grappling with standard works on pharmacology, share Elia's affection for big books. "And you my midnight darlings, my Folios! must I part with the intense delight of having you (huge armfuls) in my embrace?" In his preface Professor Burn rightly deplores the fact that "almost all medical textbooks are longer than they should be." He might have added that too few teachers seem to appreciate the student's difficulty when confronted with the task of reading a completely new subject. This is a readable little book, and despite its brevity it has the merit of being comprehensive and up to date. It should prove invaluable as a companion to standard textbooks on the subject; but the student who thinks that these lecture notes provide a convenient substitute for the "huge armfuls" is courting disaster by underestimating the perspicacity of his examiners.

Hutchison's Food and the Principles of Dietetics

(10th ed.) V. H. MOTTRAM, M.A., formerly professor of physiology, King's College of Household and Social Science, University of London; GEORGE GRAHAM, M.D., F.R.C.P., consulting physician, St. Bartholomew's Hospital. London: E. Arnold. 1948. Pp. 727. 21s.

TEN years ago, general nutrition occupied about a seventh of this book; today—reflecting many important advances—it occupies more than a third. New chapters on the hygiene and processing of food insist refreshingly on the variability of the individual and the uncertainty of much of our knowledge. Professor Mottram might have explained earlier, though, that the figures given by the National Research Council of the U.S.A. are not requirements but recommended allowances—"a tentative goal towards which to aim." Much of the dogma which mars books on nutrition is absent here, but a little remains. It is not at all certain, for example, that vitamin C really is concerned in the oxidation-reduction systems of the body; indeed, several items in this first section of the book are out of date.

The section describing the properties of food distinguishes this book from almost all others concerned with dietetics, and is extremely useful. One or two other sections are less satisfactory, but also as a whole this classical work still keeps its place among the best and most informative books on the subject.

The Aseptic Treatment of Wounds

C. W. WALTER, M.D., assistant professor of Harvard University. New York and London: Macmi 1948. Pp. 372. 45s.

As the late Elliott Cutler says in his foreword, this contains "information of the utmost value to who is concerned with the surgical care of pati whether it be the surgeon, the nurse, the medical st or the hospital superintendent." It describes the ciples of aseptic surgery and the methods of principles into practice. Surgeons are apt to accept sterilised dressings, powders, gloves, and other mat handed to them as unquestionably sterile inquiring into the methods used for making them The intricacies of this apparently simple procedure soon realised by anyone responsible for setting arrangements for carrying out aseptic surgery. book goes into the technique of sterilisation in all aspects and also into the details of procedure in the operating-theatre and the wards. Moreover step of the nurse or surgeon is depicted in clear drawings. The teaching in this book will provide a basis for the instruction of nurses, students, dressers, or others who are to take part in operations.

Textbook of Anæsthetics (7th ed. Edinburgh: E. Livingstone. 1948. Pp. 568. 30s.).—This book by Dr. R. J. *Minnitt and Dr. John Gillies has become one of the* textbooks in the English language. In addition to a revision of the text, the section on local and regional ana has been enlarged, and a useful chapter on curare has added.

Recent Advances in Cardiology (4th ed. J. & A. Churchill. 1948. Pp. 454. 24s.).—Dr. Terence and Dr. Curtis Bain have entirely rewritten this new which is naturally longer than its predecessor of 12 years. The authors' own views are interwoven with, though largely subsidiary to, a large number of references to work; no important modern paper remains unquo however briefly. The chapter on congenital heart dise deals relatively fully with a topical subject in which kn and treatment are now advancing hand in hand; and chapter on the latest methods of cardiography unipolar leads and vector cardiograms.

Cardiovascular Diseases (2nd ed. London: Heinem Medical Books. 1948. Pp. 743. 63s.).—In its new edi this book is at least twice the length of the first, and has now become a comprehensive textbook of cardiology. A considerable section on peripheral vascular dis has been added and also a large bibliography. Prof. David Scherf and Prof. Linn J. Boyd, of the New York Medical College, quote workers of all nationalities, yet have their own clear-cut views on all aspects of the subject; and *it is this imprint of their* personality which gives the book a welcome freshness. Its clear and thoughtful style (apart from one or two ambiguities which persist from the first edition), and the attempt to assign a physiological reason for symptoms whenever possible, give it a place in the front rank of cardiological textbooks.

Diseases Affecting the Vulva (3rd ed. London: H. Kimpton. 1948. Pp. 204. 25s.).—Written by a dermatologist of wide experience, this useful book provides for other dermatologists a systematic text on skin conditions of the vulva, and reminds the gynæcologist that vulvar lesions are identical with lesions elsewhere on the skin surface. Dr. Elizabeth Hunt points out that abnormalities of the vulvar skin may well be localised manifestations of a general reaction or due to local irritants—often used in the course of mistreatment. The gynæcological aspects are well presented and the coloured photographs reliable. Caruncle, however, is an *exception*, and there is no mention of the excellent results which follow extended lymphadenectomy for carcinoma of the vulva (Bassett's operation). Dr. Hunt believes that kraurosis vulvæ is only a late or modified stage of leukoplakia which is itself lichen sclerosis modified by site. With this in view, she deprecates the use of excessive œstrogen dosage in *this* and allied conditions, and advises against vulvectomy, except in the case of proven carcinoma. As before, many useful prescriptions are included in the text and a general review of therapeutic methods is given as an appendix.

be attempted he cannot be severely criticised example has proved to be ill chosen: he reveals the need for fuller study by a team of in close touch with the subject. But this is erm policy. Dr. COHEN, like the rest of his gues on the Working Party, leaves us with no diate plan for dealing with the nursing crisis.

Myelomatosis

the story of a day in the life of a professor of ine, broadcast a few weeks ago, the professor ısing a sternal bone-marrow smear to diagnose a f myelomatosis when X rays showed no evidence disease. This feat, unusual for any clinician, bly surprised the medical members of the nce more than others, because myelomatosis—ltiple myeloma—calls up a picture of a patient severe back pains or pathological fractures, in X-ray examination reveals typical "punched- areas in flat bones and the diaphyses of long , and who has Bence-Jones proteose in the . The professor, however, was quite right lly astonishing since Prof. L. J. WITTS was the r), and he was citing yet another disease in marrow biopsy has helped to clarify diagnosis uncover many previously unsuspected cases. as LICHTENSTEIN and JAFFE[1] have pointed out, vell-known picture represents the exception rather the rule. Proper diagnosis of myelomatosis has than academic interest since there is now some of treating and at least arresting the disease.

fore bone-marrow biopsy became widely used lomatosis was deemed a rare disease. WALLGREN[2] weden could collect only 66 genuine cases between and 1920; GESCHICKTER and COPELAND[3] at as Hopkins found 425 cases in the eighty years re 1929. ROSENTHAL and VOGEL[4] in New York 3 cases in nineteen years up to 1935; but in less three years after this date, when marrow biopsy used, 13 cases were diagnosed. The bone-marrow nges are easily recognised: large numbers of ma cells of normal and abnormal types are ent; the abnormal types have been named by e "myeloma cells," but most agree with DIGGS SIRRIDGE[5] that all the cells are variants of sma cells. Now plasma cells can be found in all numbers in almost every marrow smear, but y are increased only in a very few conditions apart m myelomatosis, and in these others the abnormal es do not appear. Armed with this new knowledge has been possible to diagnose forms that were not ught to be this disease at all. There has also n some simplification; different cellular types of elomatosis were described, but since marrow biopsy introduced[6] only one form of myeloma— plasmacytoma—has appeared. AEGERTER and BBINS[7] consider the evidence for distinguishing erent forms very doubtful and suggest that the ne plasmacytoma is more accurate, and LICHTEN- IN and JAFFE agree that all forms of myelomatosis are variants of a single disease complex. APITZ[8] is generally credited with the first clear definition of the unity of the various clinical and pathological types of myelomatosis. The most localised form is the "solitary myeloma," in which a tumour appears most commonly in a long bone or a vertebral body and presents either as a tumour or because of a pathological fracture. But a careful search often reveals other small tumours, and in some cases the sternal marrow shows plasmacytosis. The next stage is the classical multiple myeloma with numerous small plasma-cell tumours and a general increase of plasma cells throughout the bone-marrow. The early clinical picture of this type may not suggest bone disease at all. Backache, pains confused with sciatica, or vaguely localised pains dubbed "rheumatism" are common. Other patients may present as a "blood" disease with anæmia, epistaxis, and weakness as the prominent signs; these patients are diagnosed early, as sternal-marrow puncture should be part of the investigation; they also have bone pains. especially backache. Then there is a form in which there is diffuse replacement of hæmopoietic marrow by masses of plasma cells. This generalised form has only been recognised through marrow biopsy; the patients have an insidiously progressive weakness, loss of weight, pyrexia, and anæmia; X-ray films show demineralisation of bone which is often reported as "senile osteoporosis." Finally, there is the rare generalised form in which plasma cells appear in the peripheral blood —the so-called plasma-cell leukæmia. One of the odd features of myelomatosis is its association with amyloid deposits, sometimes only microscopic but sometimes macroscopic and occurring in unusual places. LICHTENSTEIN and JAFFE found amyloid in 10% of their cases; and KOLFF and DHONT have suggested that "primary" amyloid disease (paramyloidosis) may really be an unrecognised form of diffuse myelomatosis; the patients often have Bence-Jones proteinuria and hyperglobulinæmia.

Biochemical changes are often striking in myelomatosis. Bence-Jones proteose in the urine and a rise in serum globulin and serum calcium are the most notable, but none of these is constant or necessary for diagnosis. Bence-Jones proteosuria is absent in many cases; estimates of its incidence vary from 65% to less than 10% of cases. GUTMAN[9] says that serum calcium is raised in 30–50% and serum proteins in over 50% of patients; renal obstruction may raise the serum inorganic phosphate. These changes are not correlated, for a patient may have a high serum protein but no Bence-Jones proteosuria, and so on. The diagnosis of myelomatosis, when X-ray findings are not clear, consequently depends more on sternal-marrow biopsy than on any other investigation. When the physician is faced with a patient aged between 40 and 60 years with pyrexia of undetected origin wasting, backache, and possibly anæmia and epistaxis, myelomatosis should be kept in mind and looked for

Treatment of myelomatosis with stilbamidine (4, 4-diamidinostilbene) was first reported by SNAPPER in New York in 1946. Stilbamidine was designed for the treatment of kala-azar, and, because in this disease the serum globulin is high, it was thought

McELLIGOTT and his colleagues,[4] at St. Mary's Hospital, Paddington, treated 275 patients for primary or secondary syphilis with 2·4–4 million units of penicillin over seven to twelve days, followed in most cases by 12 injections of neoarsphenamine and of bismuth during six to ten weeks. About half of these patients were followed for twelve months or more, and the remainder for shorter periods. During this time there were 11 cases (4%) in which treatment was known to have failed. Severe toxic effects from the arsenicals occurred in 10 cases. In Montreal MARIN and others[5] treated 201 patients for early syphilis with 2·4 million units of penicillin given in a week, followed by 4 injections a week of 60 mg. of arsphenoxide and 2 injections a week of bismuth during a period of five weeks. Three-quarters of the patients were observed for six months or more. The treatment failed in 9 cases (4·5%), and the outcome seemed doubtful in another 6%. One patient died from arsenical encephalopathy. Both these studies concern too few patients followed for too short a time for definite conclusions to be drawn from the results.

Penicillin has not proved an unmixed blessing for those who treat syphilis. When it is given for the treatment of gonorrhœa in patients who are incubating syphilis the early signs may be delayed or even suppressed. In the same way, the wide use of this remedy for all kinds of infections, major and minor, must mean that syphilis will be masked, and may produce a considerable crop of late syphilitic manifestations in the future.

How Many Nurses?

Mr. JOHN COHEN, PH.D., whose minority report[6] as a member of the Working Party on the Recruitment and Training of Nurses has just appeared, asks us to pause and consider, not how many nurses we would like or think we need, but how many can in fact be obtained from the woman-power of the country. Nor would this give the complete answer: we have to consider, too, how many nurses we can afford. A planned health service, as he points out, "presupposes a planned economy in which a correct proportion of our national resources is devoted to health." As an impoverished country, we must bear in mind that what we spend, however advantageously, on medical services will have to be saved on something else, and we shall have to decide what that is to be. Even if the Treasury were inexhaustible, the supply of women is not. Nursing—like teaching, secretarial work, the social services, the medical auxiliary services, and other occupations open to intelligent women—can only hope to enrol its "fair share" of candidates; and what that fair share may be, he suggests, has never so far been determined. We have yet to discover the optimum number of beds per 1000 of population, and the optimum number of nurses needed to look after them. These things should not be matters of opinion but matters of ascertainable fact.

Pursuing the question whether it is economically justifiable to employ more nurses, Dr. COHEN endeavours to compare the "output" of different h tals which have different ratios of patients to staff. it could be shown that patients return to work s after treatment in hospitals having relatively l nursing staffs, then we might have evidence that community could profitably spend more of its res on employing and training nurses. Arguing that " task of nurses and doctors alike . . . is, presum " to speed the patient's recovery" he takes as economic criterion of nursing (or medical) the duration of the patient's stay in hospital. Fir that this is, on the whole, shorter in well-staffed he compares the national cost of good staffing national gain in working days saved for prod —the evidence providing him with "a prima case, on economic grounds, for substantially the number of trained nurses in general hospital Unfortunately, few will agree with the initial tion on which all this is founded—namely, that duration of the patient's stay in hospital is a factory "objective measure of the task of nurses doctors." The length of stay is in fact affected many variables other than the ratio of staff to pati Apart from the type of illness (for like groups can compared with like groups), it may vary with custom of the hospital, its facilities for investig and treatment, the pressure of the waiting-list, provision of convalescent homes, and even the of the hospital diet. Nor do the figures he supp justify Dr. COHEN's prepossession with this parti yardstick.

In 269 voluntary general training hospitals he was to demonstrate a not very striking inverse relati between the duration of stay and the ratio of tr nurses to beds. (The figures were taken from a made as long ago as 1938.) But this is in fact the piece of evidence he presents in favour of his hypo and the equivocal results of applying it to other grou of nurses and to doctors should have convinced him he had lashed himself to the tail of a red herring. the presence of student nurses, in general hosp "seems to have little or no effect on the patient duration of stay," results "offer little support for view" that the duration of stay could be affected changing the ratio of doctors to patients; and data mental hospitals (surveyed in 1934–38) suggest "an increase in trained nurses alone without increa the number of other nurses and medical staff is unlike to reduce patient stay"; whereas an increase of untrained nursing assistants per 100 beds (an additi of 800 to our total complement of such assistant "would apparently reduce stay, on the average, by much as three months." (The same effect, he believe might be achieved by adding another 200 part-time doctors to the staffs of our mental hospitals—though an addition to the full-time staff would be likely to ha no effect at all.) Faced with all this conflicting evidence Dr. COHEN argues ingeniously that the trained gen nurse is more "effective" than the student of gen nursing, whereas the nursing assistant is more "eff tive" than the trained mental nurse; and that full-ti doctors in a mental hospital fail to reduce patient st because they "sometimes tend to persuade some patien to stay on at the hospital so as to improve their condi still more"—an argument which does little to support hypothesis that the length of patients' stay is measure of the effectiveness of the doctor.

The fact that this attempt to provide a worki measure of nursing production is so questionable d not, however, invalidate Dr. COHEN's general the that we are still very ignorant about this subject and that it is time we studied it more ob Since he is concerned only to give an idea of w

practice, however good his intentions. He might liged to hold a surgery at his own home before eding each morning to the centre, and this might cause a waste of time through which his day's would suffer.

Hastings very rightly wants to avoid two standards atment inside the health centre. But by excluding rivate patient is he not in danger of fostering the that something better, or something more con- te, can be provided for the private patient at the r's own surgery? Surely our aim is to provide the possible conditions for practice inside the health s. We want this to be recognised alike by doctor atient. We shall not teach any patient the value of centres by denying him entry to them. We shall nhance the attraction nor increase the efficiency of entre by carving on its lintel "No admittance for te Patients." Once the centres are provided, we use them to their greatest advantage—use them ially to save the doctor waste of time and effort it his energies may be utilised to the full. The Act s the patient the right to obtain privately any section ooses of his medical care, and expressly permits the itioner to give private attention to patients who on having it. Anomalies are bound to arise through ery provision. But the more we try to keep separate are of the two groups of patient, the greater the ulties we create for ourselves and the greater the of man-hours we cause. In any case we could not the separation to a logical end without arriving at icrous conclusion. If we exclude the private patient the centre in person, must we also prevent his doctor testing in the centre his blood, his urine, or anything is his? Must telephone calls to the doctor be refused e centre if they concern private patients? Indeed, the doctor even ponder the problems of a private nt, or discuss them with a colleague, once he is le the portals of the centre? Each and every one of e things he can do, or have done, for his patient at State-provided hospital: why not at the State- ided centre?

eling, as we do, that there is no logical or justly lable point at which a line of division could be n, and confident that numerically the demands e on the centre by the private patient will not reat and will not in practice necessitate any discrimi- on between the two types of patient, we still believe in the first experimental centres doctors should not orbidden to treat those private patients who elect to nd there. The day-to-day experience of these centres be far more valuable than any present postulation; , if our contentions are proved wrong, and the smooth ning of these early centres founders on the rock of s discrimination, it will then be time enough to try tead the feasibility of making the doctor segregate patients and conduct his practice in duplicate from separate establishments. Time enough, if our sent opportunity has not itself been lost through greement, discouragement, and delay.

RADIOACTIVE PENICILLIN

HE prospect of growing supplies of radioactive isotopes, ounced in these columns last week (p. 469), opens an exciting and obviously fertile field for pharmaco- cal and physiological research. It is 25 years since esy[1] first applied isotopes to the study of plants, g radioactive lead. In the early experiments only urally occurring radioactive substances could be d and the scope of this powerful weapon of investiga- remained strictly limited until a method for pro- ing radioactive isotopes artificially was discovered by Joliot-Curie and Joliot[2] in 1934. In 1932, Urey and his colleagues discovered deuterium (H^2) and soon developed practical methods for the production of highly concentrated "heavy water." In the next decade radioactive isotopes of nitrogen, carbon, sulphur, phosphorus, iron, and many other elements were produced. In a relatively short time, therefore, a wealth of isotopic tools became available for the elucidation of physiological and biochemical problems which had previously defied solution. Much interesting information was soon gathered. Using radioactive sulphur, for instance, Tarver and Schmidt[3] showed that in normal metabolism the sulphur of cystine is derived, at least in part, from methionine, but not from elementary sulphur or from sulphate. Radioactive isotopes of iron have been used by Whipple and his associates[4] in biochemical and physiological studies of erythrocytes. A fascinating aspect of isotope research is the determination of the steps in the breakdown or synthesis of biologically important products by the organism. An isotope of phosphorus, P^{32}, has been used for the study of phospholipid, nucleoprotein, and carbohydrate metabolism, while thyroid function and iodine metabolism, including the rôle of the pituitary thyrotropic hormone, have been studied with I^{131}.

Thus, starting from naturally occurring radioactive lead, through the induced radioactive isotopes of many elements, organic substances have been built up containing radioactive carbon, nitrogen, phosphorus, or sulphur, and these have provided us with agents for probing the mysteries of intermediate metabolic processes in biological systems. The latest application of this technique is in penicillin research, where the mould is made to incorporate a sulphur isotope into the penicillin molecule. Rowley and colleagues,[5] while investigating the glutamic-acid uptake by bacteria, used a preparation of radioactive penicillin, made by inoculating a synthetic broth medium containing S^{35} with a vegetative culture of the Q176 strain of *P. chrysogenum*, in which the sulphur content had been reduced to a point at which it became the limiting factor in the yield of penicillin. The yield from 2 ml. of broth was 250 I.U., representing a 12% conversion of the sulphur in the broth into penicillin with a specific activity of 0·05 microcurie per I.U. It was noted that the presence in the medium of 50 millicuries of S^{35} per litre did not adversely affect the growth of the mould. A preparation of radioactive penicillin with a much weaker activity has recently been reported[6] from the United States. With their radioactive penicillin Rowley et al. demonstrated that the absorption of penicillin, if any, probably amounts to less than 10 molecules per bacterium (*Staph. aureus*).

Extending this work on penicillin labelled with S^{35}, Rowlands, Rowley, and Stewart, in this issue, report some excretion and absorption studies in cats. By giving mixed ordinary and labelled penicillin intramuscularly they found that 100% of the radioactive sulphur isotope was excreted in the urine, but the recovery of biologically active penicillin was much less. There was no evidence of any retention in the body, as the radioactive breakdown products (at present unknown) were excreted over the same interval of time as the penicillin itself. In a previous study of the absorption of penicillin given by mouth, Stewart and May[7] concluded that "the most important factor influencing the absorption of penicillin seems to be the unexplained that the drug might have some effect in myelomatosis which is also characterised by disturbance in plasma proteins. SNAPPER[10] has recently reviewed his results on 35 patients. The drug is given intravenously and a course of 15–20 injections of 150 mg. is needed. The doses are given daily unless there is renal damage when they are spaced out to twice a week. The diet has to be controlled and animal protein kept to a minimum. A troublesome side-effect is a dissociated anæsthesia in the area distribution of the trigeminal nerve, which often appears one to three months after the course of treatment. SNAPPER estimates that in four-fifths of his patients bone pains were relieved and the disease arrested; "arrest" is the correct term, for X-ray changes remain stationary and serum protein may remain high. Most of his patients relapsed within a year and did not respond so well to second courses of stilbamidine. Of the 12 patients who had been under observation for more than a year after treatment, 4 had died and 5 were classed as satisfactory and were ambulant; 5 of the 8 survivors had lived for three years since diagnosis and one for six years. SNAPPER and his co-workers showed that in patients with biochemical evidence of disturbed protein metabolism basophil bodies appeared in the cytoplasm of the marrow plasma cells when the stilbamidine dose had reached about 1000 mg. Histochemical spectrophotometric studies suggest that these are composed of ribonucleic acid and stilb SNAPPER suggests that the myeloma cells abnormal nucleoproteins in their cytoplasm, and stilbamidine has a specific affinity for them. amidine is far from the ideal therapeutic agent myelomatosis, for its action is only partial and unpleasant side-effects, but groundwork for ment has been laid by SNAPPER and we must that more effective compounds will be If the apparently solitary myelomas are really of a generalised disease, then the present by surgical removal and subsequent local therapy might appear wrong. GOOTNICK[11] has that there are few survivors after ten years But practice there have been many reports of surviv some years without evidence of general spread, operation may be needed to relieve mechanical ability. Perhaps evidence of extensive spread sternal marrow should be a contra-indicatio operation.

Annotations

PRIVATE PATIENTS NOT ADMITTED

IN a speech reported on p. 515 Mr. Bevan expressed great satisfaction at the fact that 92–93% of the population of Great Britain have already chosen their doctor in the National Health Service, and said that signatures are still coming in at the rate of 150,000 a week. Enrolment has indeed been far speedier than was expected. In view of the general reluctance to fill in forms of application for licences, ration books, and the like, it would not have been surprising if many more people had put off choosing a doctor, or joining his list, until the onset of illness made this imperative. Even if the rate of new entrants falls steadily from now onwards, it is very likely that by the time the winter illnesses have come and gone no more than 1 in 40 or 50 will remain outside the general-practitioner service.

This bears out our contention of a fortnight ago that the number of people who might wish to attend health centres as private patients will be very small. Some private patients will be under the care of doctors who have not taken service under the Act; others will have elected to remain private patients specifically to avoid ever going to see their doctor; not a few will be elderly people, many of whom are reluctant to change their habit pattern or to risk any alteration in their lifelong relationship with their doctor. When all such are excluded we are left with an almost negligible proportion of patients who while remaining private might want to pay an occasional visit to the health centre. On an average through the country this proportion is scarcely likely to be as high as 1% (or 40 patients among the 4000 of a fully extended practitioner). Though there will of course be areas with abnormally large numbers of private patients, these will seldom be the ones first chosen to have health centres.

Nevertheless it seems that the Minister remains convinced, as a matter of principle, that private patients must be excluded from the use of health centres—even if this ruling means that the construction of some of projected centres will be halted. In this he is by Mr. Somerville Hastings. The *Times* on Sept. 10

> "The doctors have been told that they must not private patients at a health centre provided by the authority. This is a blunder. Specialists are to be to carry on private practice at State-provided yet general practitioners are to be denied similar pr at State-provided health centres. All private p perfectly eligible to benefit from the facilities of the service and, as taxpayers, they are part-owners of the in which the work of the service is done. Why should not pay for what in any case they are entitled to get fr

Mr. Hastings on Sept. 15 replied that if the patients "are intelligent people, they would only be seen privately and pay for it if they expected to either preferential, more considerate, or better treatm And this is what they would be bound to get, so there would be two standards of treatment in the health centre." But is this theoretical reasoning by experience? In actual fact people who have el to remain private patients still seem to be content attend for some services at their doctor's surgeries, ask there no preferential attention, nor any more c siderate or better treatment than that being given to State-enrolled patients. The truth seems to be that great majority of patients remaining as private pati do so in order that they may suit their own convenie as to when, where, and how often, they consult the doctor. For certain services (e.g., recurrent minor dressings, vaccinations, ear syringing, the of priority certificates, or the obtaining of sign passports and other documents) it generally suits patients to come at a fixed, and early, time to their rather than wait indefinitely at home for his Why should they not seek similar services in a h centre? No more than now will they need or ask special attention.

If a doctor had any substantial number of patients, the fact that these were denied entry to health centre might in the end prove prejudicial to the Sabbatsberg Hospital in Stockholm. The riority of this machine lies in the excellent oxygena- which is obtained by spinning a row of plates which into a trough of blood, and so expose constantly nging thin films of red cells to oxygen (or anæsthetic s if required). On the mechanical side the machine owes h to the work of Andersson, who was also responsible the engineering aspects of the spiropulsator, which fessor Crafoord uses so successfully for giving anæs- ics during thoracic operations. The oxygen uptake he blood in Björk's apparatus is much better than ny previous machines, as much as 110 ml. of oxygen g added to each litre of blood per minute. Heparin lded to prevent clotting, but careful filtration of the d returning to the animal is essential to avoid olic complications. There is a considerable break- n of red cells in such a machine, but it has been orated sufficiently to maintain the oxygen require- its of the brain of a dog for half an hour. It is wn that the aorta can be clamped distally to the left lavian artery for half an hour without any significant nage to the lower half of an animal, and thus by oping the venæ cavæ the heart can be opened tively bloodlessly.

he aim of these experiments is to isolate the human rt from the circulation while it is opened for operative edures. This new work is a great step forward, but eaves us a long way from this goal. This year an rnative approach has been exploited by Holmes ors[4] and Brock[5] in their operation for the relief of monary stenosis. Both have successfully thrust an rument through the wall of the right ventricle and lded the constricting diaphragm in the beating heart.

VETERINARY PROGRESS

HE annual congress of the National Veterinary dical Association, held at Southport from Sept. 8 .15, once again illustrated the similarity between erinary and human medicine in the urgent problems the moment. Tuberculosis, virus diseases, and monella infections are all exercising the minds of se responsible for the control of communicable eases, whether in animals or in man. Prof. T. Dalling, o became Chief Veterinary Officer in August, discussing control of tuberculosis in cattle, emphasised that e of the chief difficulties in tuberculin-testing is non-specific sensitisation to mammalian tuberculin. eps are being taken to increase the specificity of the mparative intradermal test, in which avian and ammalian tuberculins are injected simultaneously at fferent sites and the reactions compared. Extensive periments done on the specificity factors of P.P.D. berculins produced from different acid-fast bacteria ve shown that twice as much avian P.P.D. is required elicit the same reaction in bovine sensitisations as human; Green suggests that for this reason bovine P.D. might be more useful in the comparative test r distinguishing between specific and non-specific fections in cattle. Work is also being done on the emical modification of tuberculins. In a large-scale ld experiment the double intradermal test as usually rried out proved to have no advantages, but workers Northern Ireland have shown that 7 days after the jection of tuberculin the site of injection develops an hanced specific sensitivity. Less laborious and more ecise methods of detecting bovine tuberculous infection cattle may arise from this work, but already the option of the single as opposed to the double intra- rmal tuberculin test has greatly increased the amount testing that can be performed. Professor Dalling ged the importance of suitable callipers for measuring skin thickness, and now that these are obtainable they should be widely used by the Ministry's whole-time and part-time staff. There are now over a million cattle, or 13·9% of the total cattle population, in attested herds and 250,000 in herds licensed to produce T.T. milk, but various speakers demanded a more vigorous policy of eradication.

The salmonella organisms responsible for bacillary white diarrhœa in poultry and fowl typhoid seldom cause disease in man, but various new salmonella types which may cause food-poisoning in man have lately been isolated from fowls, eggs, and animals. It has been shown, too, that salmonella infection in cows and calves is commoner than was generally realised.[1] In poultry, salmonella infections call for an organised programme of agglutination-testing and attention to incubator hygiene. Incubator infection is the chief method of spread through setting eggs, the shells of which are infected by fæcal contamination. Mr. J. E. Wilson, who discussed the control of these infections, described the technique of incubator fumigation in detail; to forestall shell penetration it should be carried out as soon as possible after setting. In large outbreaks he recommended sulphonamide therapy in conjunction with other measures. Organisms which are sensitive to sulphonamides, or to one of the antibiotics, will of course be equally so, whether they are infecting man, animals, or birds; but the behaviour of the antibacterial drugs differs considerably in different species owing to variations in absorption and excretion. Thus Mr. J. Berger and Mr. J. Francis showed that, in domestic animals, 'Sulphamezathine' gives consistently higher blood-levels than equal doses of sulphadiazine; whereas in man the reverse is true.[2]

Mr. Horace Thornton, chief veterinary inspector, Newcastle-on-Tyne, contended that the standards of meat hygiene, inspection, and control are much lower in Britain than in Continental and other countries where the veterinary profession has taken a greater part in the work. He advocated routine bacteriological examinations in the inspection of borderline carcases and a greater use of biochemical tests. The adoption of such methods would result in the release of many of the carcases which, in Britain, are now totally condemned. The criteria now applied in Germany in relation to tuberculous carcases deserve critical study. Some of his specific criticisms are set out by Mr. R. F. Montgomerie, PH.D., the association's president, in our correspondence columns. With regard to home-killed meat, however, Mr. Harry Priestley[3] says there is no cause for alarm. It is a pity that animals are rarely inspected before slaughter in Britain, although many diseases which are difficult to detect in the dead animal can readily be diagnosed in life. Several speakers regretted that the Ministry of Food has not regularised the slaughter of horses for food.

Encephalitis is as complicated a subject in dogs[4] as in man. Mr. A. B. MacIntyre, Dr. D. J. Trevan, and Dr. Montgomerie showed that apart from dietary and miscellaneous causes canine encephalitis is sometimes associated with canine distemper and with a newly recognised virus infection which causes a characteristic thickening of the pad epithelium.

On Sept. 10 the association visited Liverpool University and its Veterinary Field Station, where Prof. J. G. Wright described the techniques for cæsarean section in the cow. In his view the incision should be made just to the left of the midline, and not in the right flank. Despite the weight of the abdominal contents he has not been troubled by postoperative rupture.

individual variations in the absorptive capacity of the gut." Stewart and his colleagues have now produced evidence supporting their previous contention. When the radioactive penicillin was given to cats by mouth, the urinary excretion of radioactivity was no longer complete as when the penicillin was given intramuscularly, but was reduced to 54–24% of the initial dose, while the proportion of biologically active penicillin excreted in the urine was even considerably less than this. In one cat only 24% of the original radioactivity had appeared in the urine, and as much as 59% was unabsorbed, being recoverable from the gut contents post mortem. In this case urinary excretion had not ended, but the presence of such a large percentage of the original activity in the gut after six hours strongly suggests that non-absorption from the gut is the reason for the low urinary excretions after oral penicillin. It seems, then, that attempts to improve the absorption by this route are still worth while.

MEMORANDUM ON RH FACTORS

THE doctor who studies recent reviews and pronouncements on the Rh factor may well despair of ever understanding this example of what Lord Samuel calls "the unceasing elaboration of human knowledge"; the rows of rival symbols, the genetic terminology, the "blocking" antibodies, all combine to bewilder him. Yet for the sake of his patients he must understand the practical application of this new knowledge. He will be greatly helped by the brief, informative, and inexpensive summary published this week by the Medical Research Council.[1] Without shirking descriptions of the more difficult points, this memorandum presents a clear picture of the clinical consequences of neglecting the Rh factors, and it puts subjects like the Rh subgroups and the peculiarities of Rh antibodies into their proper perspective.

After a very short historical introduction, the first section, by R. R. Race, describes briefly the various Rh groups. He points out that 95% of all dangers due to Rh blood-groups are due to the original Rh group now known as D and its antibody anti-D, and he quotes the latest figures showing that in England 83·2% of the population are Rh-positive (D-positive) and 16·8% Rh-negative. There follows a brief but thorough description of the Rh subgroups and their genetic relationship according to the ideas of R. A. Fisher. Race rightly says that anyone who makes the effort necessary to master these groups has, at the same time, achieved at least an elementary knowledge of human genetics in general. In describing the Rh antibodies the term "blocking" antibodies is dropped, since it is not clear that this is, in fact, the action of these antibodies. What is known is that anti-D, the commonest Rh antibody, exists in two forms; one form will agglutinate red cells containing the antigen D (D-positive cells) when these cells are suspended in saline solution, whereas the other will agglutinate them only if they are suspended in a protein medium—best results are obtained with 20% bovine albumin. Cells exposed first to this albumin anti-D will not subsequently be agglutinated by the saline antibody; hence the term "blocking" or incomplete antibody. But when Diamond gave intravenous injections of Rh-positive blood to Rh-negative male volunteers, he found that the saline agglutinins appeared first, and that then with repeated doses they diminished and eventually completely disappeared, being replaced by a rising titre of the antibodies detectable only in albumin suspension. Diamond therefore regards the albumin antibodies as "hyperimmune agglutinins." The authors of the M.R.C. memorandum adopt the noncommittal but tive terms "saline" and "albumin" agglutinin antibodies.

In the second section P. L. Mollison deals with considerations and covers more familiar ground. details how immunisation to Rh can be produced transfusion of Rh-positive blood into Rh- persons or by a pregnant Rh-negative woman Rh-positive fœtus. A less well-known fact is that intramuscular injection of blood—e.g., for can produce life-long immunisation. Mollison the importance of detecting Rh antibodies in the blood, since this is the best indication that the may be affected by hæmolytic disease. Two tions should be made, one early in pregnancy and about six weeks before the expected date of the first examination reveals sensitisation before pregnancy, since antibody developing for first time during a pregnancy rarely shows before fifth month. The clinical pictures of hæmolytic and of the allied syndromes are described, and the means of dealing with the situation and the advising parents about future pregnancies are discussed. The technical details of exchange fusion provide useful practical points for workers maternity hospitals.

Clinical laboratories are not at present enco to undertake Rh testing, and the regional laboratories do most of this work. However, clinical pathologists may be interested in doing own, especially if they are in situations distant from regional centres. They will obtain compr help from the third section, in which A. E. fully sets out the practical details of Rh Altogether this is a highly valuable and aut addition to the M.R.C. series of White Memoranda.

THE ARTIFICIAL HEART

ATTEMPTS have been made since the turn of century to devise a machine which would perform circulatory duties of the heart. Twenty years ago and Schuster[1] showed that this could be done, and perfusion pump that they devised and demons at University College, London, is still in use. when, in addition, physiologists sought to oxyge the blood mechanically outside the body, the task be much more complicated. So far the only fully effic oxygenator has been the isolated lungs. Some of earlier attempts at artificial oxygenation now seem rath crude; hydrogen peroxide and oxygen have injected into the blood-stream, while oxygen-carry solutions of various kinds have been tried. The intr venous injection of oxygen, unless performed slowly, carries a severe risk of embolism. A differe type of experiment followed the demonstration Hartridge and Roughton that hæmoglobin would take oxygen much more readily in solution than when enclo in the red cells. But as would be expected, anim perfused with solutions of hæmoglobin rapidly died. the hæmoglobin passed into the urine and lymp Further attempts were based on the principle by nature in the lungs—the exposure of a thin film red cells of large surface area to oxygen. Perhaps most outstanding experiments were those by Bar and his co-workers[2] and later by Daly,[3] but neither their thin-film methods was suitable for mainta an animal for long.

The recent advances in intracardiac surgery stimulated renewed interest in cardiop machines. In this issue Dr. Björk describes which has been evolved in Professor Crafoord's

Medical Supervision in Industry

H. A. DE BOER, of the International Labour , said that international conventions are a stimulus tional legislation. Before the Medical Examina- of Seafarers Convention in 1921, only six countries egislation protecting seamen, but the convention d nearly all countries to adopt protective legislation. dical supervision of the worker is being developed any countries, and in most of Europe and in the . it has reached a high level of efficiency. The ulties of the pioneer in industrial medicine in Western tries have been slight, however, as Dr. H. P. DASTUR ed, compared with those now being experienced he few men and women interested in industrial cine and nursing in countries like India, with their l differences and illiteracy.

European countries perhaps the greatest remaining ulty is the discontinuity in the medical services for ers at different ages. Most of them have established ol medical services, but these still need to be grated as part of the child's school life and continued ugh the years of adolescence in industry and merce. The vast amount of non-absent morbidity ng adolescents is seldom realised.

r. W. G. DONALD (U.S.A.) gave an account of the ersity of California's student health service, which a lavish scale. If the American adolescent coming privileged homes is in such need of help, the opean adolescent coming from less privileged homes earning his living must need much more. Here is of the opportunities of the county colleges, which, er the Education Act, 1944, will shortly be established npulsorily in Great Britain. Adolescents dispersed large number of small factories will, for one day a k, be collected into a functional group which could be ject to guidance and medical supervision. Mr. F. W. , headmaster of a day continuation school, laid at emphasis on the fact that if " black-coated workers not to be superior to black-handed workers " both schoolmaster and the doctor have a great part to in building up group morale. Elaborate schemes the examination and treatment of adolescents are little importance compared with the feeling that the ctor and nurse, working either in industry or in a unty college, are part of the adolescent's life.

Incentives, Job Adjustment, and Absenteeism

Prof. ELTON MAYO (U.S.A.), in a paper read by his ughter, pointed out that labour is more than a number individuals collected together. The great significance the Hawthorne experiment and subsequent experience that economists and others have failed to grasp the fect of group influences on the individual. The dividual worker is a member of a team, and statistical udies on the frequency of absence show that the rgest class is composed of those who have not been bsent at all.

Dr. T. M. LING traced the effect of psychological causes rising within the individual, which help or hinder his djustment to a social group. In a later discussion everal speakers supported Dr. Ling's plea for closer and ore extensive study of personality variations.

Dr. F. R. GRIFFIN dealt with the problem of morale, articularly in small factories. Morale cannot be onsidered as an isolated factor, for it is one that arises om the total situation.

Dr. OSWALD SAVAGE's paper, though limited to the iscussion of rheumatism as a cause of industrial dis- bility, reminded delegates, who up to now had been onsidering psychological or psychosomatic causes of bsenteeism, that a large amount of disability is caused y organic diseases, particularly those of a chronic ature.

Other speakers gave accounts of their personal experiences and methods they have adopted to reduce absenteeism. The very good results they claimed were generally felt to be a tribute to their enthusiasm rather than to the particular methods.

Work and Skill

The discussion on this subject showed a big difference in the Continental and British approach. The former, very similar to the American, places emphasis on job analysis integrated with personality profiles ; the latter approaches human relationships in industry from a sociological and anthropological point of view. The British regard the promotion and maintenance of morale as of greater importance than the technical efficiency of the worker, with or without a machine.

Sir FREDERIC BARTLETT described the development of skill, which consists in a sequence of responses subject to psychophysical or mental control and which sets out to achieve an object. The most promising approach to an understanding of practical mental skill lies in a controlled study of the conditions, both individual and social, which lead to the formulation of programmes, and of how these can be revised and altered and yet kept in touch with rapidly changing circumstances. As Mr. P. A. D. GARDNER and subsequent speakers emphasised, physical skill reaches its highest form in craftsmanship.

Dr. A. T. M. WILSON urged that doctors working in industry should be better trained to integrate the contributions of workers in other fields of social sciences.

Health and Disability

Against the background of Dr. G. E. GODBER's description of the National Health Service, delegates discussed the development of health clinics in industry and the part that medical supervision plays in the successful employment of the limited or disabled employee.

Dr. F. E. POOLE (U.S.A.) spoke of the need to emphasise not the disability but the ability of each patient : the whole personality, rather than a specific disease or disability, has to be assessed, expressed in simple terms, and related to a flexible system of job classification. The importance of this was apparent in Prof. TOM FERGUSON's account in the employment of disabled persons in Hillington. Details such as lavatories with hand-grasps for use by men without legs are important if disabled men are to feel personal independence within the factory. The success of such experiments is to be judged with the regularity of attendance (at Hillington only 5·7% of working days are lost from all causes of absence), economic production, and the development of social and extra-industry interests among members of the group. The fact that a factory is an economic success is important from the purely productive point of view, but more important because of the feeling of usefulness it gives to disabled persons.

Dr. LOGAN thought that many of the systems of estimation and classification of disablement place too much emphasis on surgical disabilities : in view of the large numbers of persons suffering from peptic ulcers, chronic bronchitis, and degenerative conditions, more attention should be paid to the medical aspects of disablement.

Dr. L. ROCHE (France) in the closing paper, emphasised that production can be considered an index of health and well-being in its widest aspects.

Hazards of Particular Industries

Dr. J. GREGORY, who read Dr. GEORGE FLETCHER's paper and amplified his remarks on byssinosis in cotton workers, pointed to the need for studying the early development of pulmonary symptoms among such workers.

INTERNATIONAL CONGRESS OF INDUSTRIAL MEDICINE

Last week we briefly described the opening meeting at which Lord Moran, P.R.C.P., presided and the 900 delegates from more than forty countries were welcomed by Mr. George Isaacs, Minister of Labour, and by Mr. T. E. A. Stowell, F.R.C.S., first British president of the Commission Internationale Permanente pour la Médecine du Travail. Mr. Stowell paid a special tribute to the work of Prof. L. Carozzi, who was responsible for forming the commission in Milan in 1906 and has been its secretary-general ever since.

The following report describes some of the many sessions held from Sept. 13 to 17. At a crowded final session Lord Webb-Johnson, P.R.C.S., presided, and Mr. G. R. Strauss, Minister of Supply, gave the closing address. Prof. P. Mazel expressed the thanks of the delegates for the hospitality of the British Council, and said that the health happiness of the workers in this country is an exp of national well-being and an achievement of industrial medical officers, nurses, managers, and working in industry may well be proud.

Social events included a big Government at Lancaster House on Tuesday, and a reception by Royal College of Physicians on Friday evening. the same day Mr. H. E. Griffiths delivered at House the Mackenzie industrial health lecture, e The Surgeon in Industry. During the present the visitors, in small groups, have been visiting tories, institutions, training centres, and ind undertakings of many kinds in England, Wales, South-west Scotland.

The Law

A session on the industrial medical content of the law produced a vigorous discussion. After Mr. MOELWYN HUGHES, K.C., and Dr. P. PRINGLE had described the English law relating to industrial medicine and compensation, Prof. L. CAROZZI (Italy), the chairman, dealt with current industrial legislation in other countries. Everywhere, he said, the application of labour legislation meets with difficulties, as shown in the reservations made by the committee of experts of the International Labour Organisation on the application of conventions. It needs good will on the part of governments, employers, and workers to attain the aim of such legislation, which is the common good and the team spirit. He thought that laws relating to health and hygiene should be revised and codified; often the regulations are too numerous and sometimes they are contradictory. Today social-security laws tend to embrace both compensation and the prevention of accidents and industrial diseases, a state of affairs which makes the application of industrial legislation more complicated. In fact the medical supervision and prevention programmes allotted to social-security departments encroach on the rights and duties of the technical and medical factory inspector and of the works medical officer. Though the legislators envisage a permanent liaison between the two functions, the methods adopted are not satisfactory. He instanced the difficulty which French workers encounter in obtaining compensation, because industrial diseases have been too precisely defined; the social-insurance department has plenty of money which is not distributed in compensation as it ought to be.

Dr. I. URBANDT (Argentine) read a paper on the regulation of hygiene and safety in factories, and Dr. CATHERINE SWANSTON reviewed the protective legislation for women and young persons in industry. She said that the factory inspectorate, established in 1833, is responsible for much reform of the hours of work of women and young persons, but even now the law as it stands in relation to their employment is in many respects out of date, illogical, and uneven in its application.

One of the main points arising in the discussion was whether compensation laws should be general, with details in more flexible codes, or whether the compensatable illnesses or accidents should be precisely defined and scheduled as in the French and in a lesser degree in the English law. Some speakers feared that if the compensation laws were interpreted in a flexible manner the workers might exploit the compensation funds, but others saw little risk of this provided careful medical examination establishes that the morbid conditions are directly due to the occupation.

Organisation of Industrial Medical Services

Prof. P. MAZEL (France) reviewed the organisati industrial medicine in France and pointed out th a law passed in October, 1946, all establishments, soci and associations employing paid workers, wha their number, must arrange for medical services for workers. Any registered doctor may be chosen by employer or industrial committee to carry out the d his payment being made at a standard rate by employer. The doctors' duties consist in the examin of applicants on engagement and also the per medical examination of all workers at least once a and more often when the worker is under 18 years age or engaged in dangerous work. Dr. Mazel described the administration of this service, which i effect a national industrial medical service.

Dr. L. GREENBURG (U.S.A.) discussed the indus health services in New York State, where there a 52,000 factories in which nearly 2 million workers a employed. Supervisory work is in charge of the Depa ment of Labour and is carried out by a factory inspect service and by the division of industrial hygiene and safety standards. The licensing of industrial med bureaux and of physicians for industrial practice i vested in the workmen's compensation board of t State. This board is also in charge of the adjudicat of compensation claims for industrial injuries and occupational diseases. Labour unions, by establishing clinics, by including health provisions in labour contracts, and by programmes of health education, greatly strengthen the movement for improved health among workers. Voluntary health agencies also play a part The United States Public Health Service, through the division of industrial hygiene, has conducted research, has aided State units in the conduct of their work, and has provided funds and personnel for developing industrial medicine.

Dr. A. BRUUSGAARD spoke on the industrial medical services in Norway, which cover 17% of the employees in industry, commerce, and transport (exclusive of shipping).

Almost all firms of more than 500 employees are covered, and a fifth of all firms with more than 50 employees now have a medical service. The scheme has been set up by a voluntary agreement between the Norwegian Federation of Labour, the Employers' Association, and the Norwegian Medical Association. This voluntary aspect is regarded as of the utmost importance, to ensure the development of a democratic system.

Dr. A. NYYSSÖNEN gave an account of the industrial health service in Finland, and Dr. N. L. LLOYD described the organisation of the British Ministry of Supply medical service.

g radiations; but a committee in the United have made some which they considered to be on fe side. For ordinary X rays and gamma rays the sible limit for exposure of the whole body was per week, measured in air; for exposure of the it was only 1 r. per week, and for exposure of the body once in a life-time it was 25 r. for persons years of age and 50 r. for persons over 45. For ry beta rays the limits are equivalent to the in terms of energy absorbed per gramme of tissue level of the reacting skin cells. For fast neutrons nits of exposure are related to a biological effective- ictor which is 10 when the measurements are made ms of energy absorbed in tissue; for slow and al neutrons the biological effectiveness factor is 5.

P. C. **Koller** described the chromosome fragmenta- nd the disorganisation of cell division caused by ig radiations from X rays, gamma rays, neutrons, lpha particles. The changes in the cells often in their death and cause lesions in tissues which ow in repairing. Controlled therapeutic doses of ion may be employed to destroy cancer tissues gh the damage induced in the mechanism of cell- on responsible for malignant growth. The changes ed by ionising radiation are not necessarily lethal e cell; it may be only the distribution of the nosomes which is altered. Tissues derived from cells will be abnormal in their genetic constitution. ng radiation may induce changes in the "gene." se occur in genes borne by the chromosomes of the or ovum they will be transmitted to successive ations and spread in the species. Experimental nce tends to show that in all living organisms ic or hereditary changes are induced by irradiation, hat man cannot be an exception. The magnitude e effects depends on the dose of radiation; these s are cumulative and can be mitigated only by ous protective measures. It is therefore not gh to confine such measures to the protection of iduals; the genetic well-being of future generations major issue which must be equally considered when ctive measures are devised.

. W. **Binks** spoke about the part played by the onal Physical Laboratory in safeguarding the health orkers exposed to radiations. The service offered ded examination of dental films carried by all sers exposed in factories and laboratories to radio- re materials and X rays. Experts from the National sical Laboratory go out and measure the actual ations in the workplaces.

r. L. H. **Gray** asked Dr. Failla what is the basis stimating the permissible doses of radiation and what the actual absorptions by human beings as opposed animals in experiments. He thought that care ld be taken that the limit is not put too low. He asked whether skin cancer from radiations can arise hout there being any previous burn of the skin. eply, Dr. **Failla** instanced the case of a technician whom blood changes began within two years of sure to an estimated radiation of 1 r. per day. is opinion a limit of 0·3 r. per week is not too low. cancer can arise without previous burning of the .

r. **Ethel Browning** asked about the effect of ll doses of radiations. In her examinations of the d of all luminisers in the country, whose exposure found to be low, it appeared that there was a ulating effect on the blood from small doses and that ous cells appeared in the blood picture which were the nature of immature monocytes. This effect eared to be transitory, for similar cells were not d in her follow-up examinations of luminisers who left the industry. Prof. J. S. **Mitchell** said these abnormal cells are difficult to classify, and we should lay stress on changes in total cell-counts rather than on counts of abnormal cells. He pointed out that skin cancers due to radiation appear on the dorsal aspects of the hands rather than on the flexor surfaces where atrophic changes occur. The time, he thinks, has come when the biochemists should become interested in the effects of radiation.

Mr. K. L. **Goodall** outlined the practical problems that arise in guarding workers in factories from the effects of radiation, and he mentioned the Luminising Regulations drawn up by the Factory Department.

Dr. J. J. **Nixon** (U.S.A.) regarded the blood-count as a frail reed on which to assay the chronic effects from radiations. So many things affect the normal blood-count. One should pay attention to the trends of the blood-counts and the trends of the blood pictures in groups rather than in individuals. Other methods of investigation need to be developed.

Dr. **Katharine Williams** thought it important to know the permissible limit of exposure in a life-time, particularly for workers engaged in screening in X-ray rooms; and Dr. W. C. Cox (U.S.A.) described how in the U.S. Army records of all X-ray exposures are kept so that more accurate knowledge may be obtained on which to lay down limits of exposure.

Disabilities

13. PULMONARY TUBERCULOSIS

During my first hospital appointment as a student I had a routine Mantoux test, which was negative. Four months later I had a series of hæmoptyses lasting a week, and a bad X-ray film did not show distinctly the lesion that was subsequently found in a much more advanced state. Three negative sputum tests and a normal sedimentation-rate, together with a normal axillary temperature convinced the senior physician that the blood came from my nose (not examined); and after a fortnight's holiday I returned to ward work. During the summer I continued with my athletics, representing my country, and in the autumn I started training for the rugger season, during which I was expected to get an international cap. However, the war began and I was put on night duty. My finances were not good, and I began to spend less on food so that I had more for Saturday nights after rugger.

Definite symptoms appeared eighteen months after I had gone to my hospital. I could not get "fit," my "wind" was not good, I had a pain in my left side, and I began to cough. There was quite a lot of purulent sputum, which I was assured came from my sinuses, so I had a submucous resection and antral puncture. Soon I noticed I was losing weight, had indigestion, and my temper was awful. I started nightmares and night-sweats, and my voice was husky all the time. The pain was now acute and did not respond to heat, so I saw a doctor who found signs of cavitation. When he screened me and said "There's a cavity as big as a golf-ball, with a fluid level" my first instinct was to escape—to join a ship, anything rather than face the facts. My medical student friends firmly made me stay in bed and arranged for my admission to my teaching hospital. The local tuberculosis officer called to see me and arranged for an X-ray examination of my friends. It was a great relief to learn that none of them had been infected.

In hospital I was kept on "absolute bed rest," which probably did more harm than good since I could not read for long, and when I did have visitors I got overtired and had a much higher temperature than usual. A lot of my time was spent in a trough of depression, thinking how I could prevent my friends at home hearing of my condition and how I could redeem myself for the awful

The risk of boot and shoe operatives catching tuberculosis depends on the spacing of workers on a factory floor; but Dr. ALICE STEWART's findings, which confirm the presence of a high incidence of tuberculosis in the Northampton boot and shoe trade, show the necessity for further investigations in other industries and more work on the epidemiology of tuberculosis.

Dr. PATRICIA SHAW pointed out that the gross mortality figures of shop assistants do not differ—except in specific instances, such as grocers—from those of the general public. A significant fact is the disappearance of men of the age of 30 and onwards from the distributive trades. She would like to think that this is because shop assistants become proprietors; but experience shows that this is not so. Probably, because of the frustrating nature of their work, shop assistants drift into other occupations. Much more study is required to decide simple problems such as whether the incidence of varicose veins is higher in shop assistants, who stand all day, than in other occupational groups.

Occupational Tumours of the Bladder

Prof. G. H. GEHRMANN (U.S.A.) described experiments on dogs confirming other work on the carcinogenic action of beta-naphthylamine; but no tumours could be produced with aniline, benzidine, and purified alpha-naphthylamine. Dr. G. M. BONSER spoke of her experiments on the induction of tumours with beta-naphthylamine, and confirmed hitherto uncovered results with the other amines. Prof. G. DI MAIO (Italy) from a considerable experience of these tumours, gave an account of the clinical and cystoscopic appearances, the highest incidence being among benzidine and alpha- and beta-naphthylamine workers. Prof. E. C. VIGLIANI and Dr. M. BARSOTTI (Italy) presented the results of observations among chemical workers from which it appeared that beta-naphthylamine and benzidine are both causes of tumours.

Dr. ACHILLES MÜLLER (Switzerland) summarised an experience of some thirty years in this disease, and indicated that the modern approach to manufacture, combined with routine cystoscopic examination, has led to its being mastered. Dr. CORNELIO BELLESINI (Italy) detailed a process of manufacture of benzidine in which workers have not developed any tumours even after twenty years.

The position in regard to these tumours in Britain was described by Dr. M. W. GOLDBLATT, who asked for an equitable system of compensation for workers who develop them.

Diseases of the Lungs

In a session on diseases of the lungs other than pneumoconiosis, Dr. T. A. LLOYD DAVIES described his clinical and experimental investigations into manganese pneumonitis, and Dr. K. M. A. PERRY read a paper on bagassosis.

Prof. A. POLICARD (France) spoke on his animal experiments on the effect of beryllium in the lungs. He found that beryllium sodium fluoride dusts provoke early and violent pulmonary œdema, resulting in death of the animals within 24 hours. Beryllium oxide dusts, on the other hand, cause hyperplasia of the mesenchyma of the lung tissue. Three types of reaction are found, the first being histiocyte pneumonia, the second granulomatous nodules, often with giant-cell formation, and the third cellular thickening of the alveolar walls. The granulomatous nodules seen after a few weeks' exposure persist for several months. Metallic beryllium and beryl do not seem to affect the lungs of animals.

Dr. E. H. SCHIÖTZ (Sweden) described the metal fever produced by copper dust. He preferred the name of "metal fever" to "metal fume fever" because in his experience the condition is produced by dust and not by fume.

The monocytic infiltration induced in animals' l by the introduction of manganese dioxide and bery oxide suggests that pulmonary lesions in men e to these dusts may be due to the same basic proc despite clinical differences. It seems, too, that b sosis, farmer's lung, broken wind in horses, and per byssinosis, have a similar ætiology, as allergic condi manifested as an acute bronchiolitis.

Toxicology

Dr. A. U. JORDI (Switzerland) gave an accoun psychic disorders in industrial poisoning and referre what he called a psycho-organic syndrome commo industrial poisoning by lead, mercury, and many o solvents. The main features, he said, are loss of me for recent events, slackening of all mental proc depression and narrowing of interest, nervous irritab rapid changes of mood, and insomnia. In me poisoning tremor is the most obvious symptom; progresses after removal to safe work, whereas in po ing by organic solvents the symptoms usually clear the exposure has been long and severe. The change best studied in carbon-disulphide poisoning. In treatment of the psycho-organic syndrome vitamin and C and also male hormone have proved helpful.

Dr. M. BARSOTTI and Dr. G. CROTTI (Italy) spoke epileptic fits in workers handling T.4. powder (methylenetrinitroamine), and Dr. R. A. MCFARLA Dr. NIVEN, and Dr. HALPERIN (U.S.A.) outlined a met for estimating the effects of various substances w interfere with the oxidated mechanisms of the cen nervous system. The method involves the meas ment and correlation of changes in light sensitivity various criteria through blood analyses.

Dr. M. GAULTIER (France) discussed the ocular dist ances in cases of poisoning with methyl bromide, Dr. A. AHLMARK and Prof. S. FORSSMAN (Swed read a paper on the testing of cerebral function by me of anæsthetics.

Atmospheric Pollution

Prof. PHILIP DRINKER (U.S.A.), in a paper wri with Dr. W. A. COOK, referred to the difficu in determining the maximum allowable concentra of atmospheric impurities. The determining proc he said, is an art rather than a science, and it would a serious mistake to consider any of the method accurate. Only a few substances, like carbon monox have such well-defined systemic effects that exposures can be laid down with a high degree of precisi Most others, like benzol and carbon tetrachloride, best into zones of toxicity. He set out six such zones a number of representative substances, ranging from th least harmful (like acetone) at concentrations from to 2500 p.p.m. to the extremely toxic, like radon gas at concentrations below 0·1 p.p.m. He believed tha this classification of contaminants should help in th understanding and control of industrial health risks.

Mr. N. STRAFFORD discussed the determination of toxic substances in the air; Mr. C. N. DAVIES reviewed the history of fibrous dust filters; Prof. J. TEISENG and Dr. B. SOUČEK (Czechoslovakia) described inhalati experiments designed to determine the absorption and excretion of carbon disulphide; and Mr. H. H. WATSO dealt with the physical properties of industrial dust

Radiant Energy

Dr. HERMAN LISCO (U.S.A.), speaking on the potential hazards and pathological aspects of radioactive isotopes said that more use of radiant energy will in future b made by private research laboratories, governmen agencies, and in industry arising out of the peace-tim developments of atomic energy.

Dr. G. FAILLA (U.S.A.) pointed out that it is hard to establish accurate limits for permissible exposure t

In England Now

unning Commentary by Peripatetic Correspondents

E danger of not being accepted as medical students r troubled us in the bad old days. So long as we l produce evidence of average scholarship and a *master's testimonial* we were *reasonably certain of* ace. My year did, however, spend an anxious and uncomfortable Registration Day. We attended at *appointed time and soon the waiting-room* was ed with would-be students. Slowly and at first reasonably orderly manner we passed one by one the Dean's office. Then the rumour started—that a limited number of students would be accepted, first-come first-served basis. Instantly there was s, and most of us packed into the corner of the a nearest to the Dean's door. We stayed like this several hours, a sharp struggle for priority breaking each time the door opened.

he danger of non-acceptance may have appeared real to us at that time but it was a ridiculous and gnified performance. The female applicants and a lful of older men stood aloof from the mêlée, and, y years later, one of the latter told me how he had ed the scene with near incredulity, wondering how earth this pack of rowdy youths could possibly be sformed into responsible doctors in the short space x years. As an observer within the group he could y us closely as awkwardness left us, poise and confidence grew, and tidiness of dress began to me some importance in our lives. He found the sformation astonishing.

a the modern sense we were not selected at all; were just a group of middle-class boys who were er clever enough to win scholarships or whose fathers e well enough off to send us through medical school. were a pretty average bunch, probably representative the usual intake at provincial universities. A few by the wayside and never qualified, but the proportion not high and I have yet to hear of a contemporary mine who can be regarded as a professional misfit. haps we were better than average or perhaps (dare hisper it?) the danger of wastage has been overphasised in an attempt to make the best of a situation ich current overcrowding has forced on us.

* * *

The following reflections on the Health Act should sung in a West Country dialect to the air of "Villikins d his Dinah."

When I were a boy I were not very smart.
So they takes me and learns me the doctorin' art.
A general practitioner is what I became
—Now I earns a good livelihood by signin' me name.

When volks comes to zee me because they veels wrong,
To wan o' these yur specialists I passes 'em along,
I writes 'em a sustifikit to say they'm diseased
And the patients and the Minister is vurry well pleased.

If yur boy bain't azackly, if 'e bain't vurry bright
You do what I tells 'ee and then you'll do right—
Jest send un and larn un thiccy doctorin' game
—An' 'e'll earn a good livelihood a-signin' 'is name.

* * *

Examinations are in the *news again. Candidates* iticise: Censors condemn. But I go on taking them. few nights ago the American Ambassador and I sat own to take the written part of the *Conjoint finals.* ust the two of us. The invigilator provided him with large quantity of paper and me with a pile of souplates. One cannot write rapidly or legibly *on a soup*late whichever way up it is and naturally the time pired before I had even completed one answer. Last ight I faced two examiners (one an old enemy of ine) across the green baize. He handed me a specimen. What is that?" he said. "It looks to me," I replied ithout hesitation, "like a piece of melon—or possibly," added as an afterthought, "paw-paw." He remained npassive. "You could not be further from the truth," e said, and walked out of the room. His co-examiner tared at the ceiling like the Frog Footman and said nothing. Once more the precious minutes ticked remorselessly by.

Before the trick-cyclists murmur condescendingly, "Elementary, my dear fellow," let me say that I have *no further examinations to take. Why then, should I* dream thus? Sometimes my pen runs out of ink; often I am disturbed and cannot concentrate; always the bell *goes before I have really started. A frightful thought* strikes me. Perhaps the Minister is planning a compulsory examination for all State doctors. But then, aren't all the best *soup-plates going for export?*

* * *

Finding a one-eyed man lurking in the hospital corridor I asked his business. In a Yorkshire accent he inquired whether I was the "vile diseases doctor." Ruefully admitting that I might be so described I was shown a *long-standing* ulcer of the leg, *one of a series of* gummatous incidents which were part of the man's very existence. He told me that he had been covering the ulcer with cobbler's wax and strapping it over with insulating-tape. Rather superiorly I informed him that modern treatment would soon take care of it if he attended very regularly. As it proved, he developed skin sensitivity to iodides, his oral condition limited the bismuth, and his dermatitic skin made one hesitate with arsenic. Penicillin was a disappointment and after three months the ulcer was as punched-out as ever and he was put on mercury as a last resort. During this time he had countless hospital applications and not a few of his own little-known proprietary unguents which on occasion I even had copied in the dispensary.

At last one day the ulcer showed indisputable signs of healing. "I knew it would, doctor," he said, "provided we had patience. But if I had been living in Hull it would not have taken a quarter as long." The last bit was rather a damper but I had to ask why. It appeared that some years ago when suffering from similar trouble he had taken his watch to be repaired at a shop in the back streets of that Yorkshire city. While he was inside the man behind the counter asked about his leg, inspected it, and announced that he could cure it in a fortnight. He retired to the rear of the shop and returned with some ointment in a boot-polish tin. The claim proved no idle boast and my patient had carried the ointment about with him for years as insurance against future trouble. He had finally surrendered it to his sister to cure a burn which was proving resistant to the machinations of her panel doctor. "I should never have parted with it," he concluded as he rose to go.

* * *

I was rather saddened by your correspondent describing how he had extracted a tooth. Out here in a Newfoundland outport (in Newfoundland outport means anywhere outside St. John's and corresponds to the provinces in England) I am 200 miles from a dentist, so I extract anywhere up to a hundred and fifty teeth a month. The difference between a doctor and a nurse is that a doctor is expected to be capable of doing a mandibular block. My patients order dentures from a mail-order firm in Chicago. They write away and are sent wax to take impressions themselves. Sometimes they come to me to do it for them. Sometimes the teeth fit, sometimes they don't. If they don't it's just too bad.

* * *

The misused idiom can also be amusing. M.O.: "Any serious illness?" Polish Fireman: "Noding sairioos—fifty-fifty ill sometimes." It seemed that "fifty-fifty" meant "slightly," for later, when I was testing his colour perception, he called the paler shades fifty-fifty red, green, or what have you; he also volunteered the information that his auditory meatuses might be fifty-fifty dirty, as he had been working in the pits recently.

> "SIR,—May I crave the hospitality of your columns to ventilate a point I was unable to thrash out owing to limited time at a recent meeting . . . ?"

Ventilation rather than castigation, by all means. But personally I prefer—if I have time—to nail my point to the mast and, with my back to the plough, steer my barque safely round Cape Metaphor and up the steep and thorny path until, at evenfall, I draw rein in the quiet reaches of Lunacy Verge Harbour.

crime of getting tuberculosis. I imagined myself an outcast, and it was not until my girl friend continued to visit me, despite all I did to dissuade her, that I realised the end of the world had not come. Eventually an eminent chest physician saw me, and at last the question of a sanatorium and the cost of treatment was raised. This was all taken out of my hands by my father, but I can imagine what a strain it could be for a less fortunately placed patient.

In time I was transferred to a sanatorium with my own room, and here for the first time I saw that one could get better. It was not that the will to get better had been lacking, but somehow one had never been given the prospect of a completely cured existence. My neighbour was a young man of similar age who had had tuberculosis before and relapsed, but was now improving. He gave me a new conception of tuberculosis—how one could live with the disease and what the limitations were. During his previous stay in the sanatorium he had wasted his time, but he was determined that this should not happen again; nor happen to me. Accordingly he argued with me on subjects I had hardly thought of, and made me buy new books on art, music, biography, and poetry. He insisted on my having a wireless set, and when eventually I got a gramophone with a lot of classical records and began to give recitals I realised how much I owed to his good advice: make the most of your time and you will not notice your illness. Furthermore, this interest in things other than sport broadened my outlook. That was before the days of art-therapy and most male patients did nothing except read detective stories. Those who were ambulant organised various communal activities and brought round the "glossy" magazines. Too much interest in communal activities is a bad thing, for it encourages the patient to feel he is important in his own little circle and to forget he has to live "outside." The "glossies" were a death symbol, the negation of all desire to get well and leave.

I had a successful artificial pneumothorax, but because of basal adhesions it was reinforced by a phrenic avulsion. The need for this had been carefully explained to me, as had the mechanics of collapse therapy, and I was beginning to take an interest in my A.P. rather than myself. This attitude is to be regretted, for patients become unduly alarmed if fluid forms and no longer consider themselves as a whole. Since my larynx was involved I was put on silence, which was very difficult to observe, especially when friends came to see me. I began to look and feel much better and to gain weight—but not self-confidence, so when I saw my parents for the first time since my diagnosis I was acutely embarrassed and felt very guilty towards them. They had been X-rayed by the authority that was paying for my treatment. I was very upset when told my brother had some infection, but a film six months later showed it had cleared up.

Life in a sanatorium, as in a gaol, imposes unphysiological restrictions, with the result that male and female patients develop "friendships" that will seldom withstand the trials of the outside world. Sometimes there is an engagement; and occasionally nurses, often tuberculous themselves, marry patients. This is a poor solution to the problem. At one time I got so immersed in the sanatorium life that I came to hate the visits of my girl friend because she symbolised the outside world with all its excitements and demands, to which I dreaded having to return.

One evening after a refill I felt rather breathless and found I had a temperature of 102°F. By the time I had called the nurse I was in great pain, hardly able to breathe, and when the doctor came I was collapsed. He immediately treated my spontaneous pneumothorax, and the next few days I was most unhappy though heavily "doped." Then followed three months' bed rest with *occasional aspirations*; but still the fluid formed, although my sputum had been negative since th was begun, the fluid contained tubercle baci quantity. Now began a period of uncertainty; I need a "thora" for my empyema or not? The said "yes" but the physician maintained there wa need in view of my good general health; so it was to wait and see.

A day came when I was allowed out of the for a walk. I set off at a cracking pace and w minutes was completely exhausted. This taught sharp lesson and I determined to find out the my exercise-tolerance. My resting pulse-rate wa and on mild exercise 100 per min. If it rose to 120 I very short of breath, but if it was higher than I simply could not move, however fast I tried to b This was a useful way of deciding whether I shoul with my walk or sit down and wait for my pulse fall. Naturally I was able to do more as I l adjusted.

When I left the sanatorium I spent some of my with a former patient and we both noticed how it was to find anywhere to sit down and rest, and tically impossible to stretch out at full length. H hotel lounges have I visited in search of a quiet when my rest hour was due! When a patient has left a sanatorium he gets tired very quickly with the of modern life; he develops a feeling of despair wishes vehemently to be back in his own cubicle, the old routine. At this period, unless he things quietly and is given a lot of enc he may relapse because of his inadequate adjustment.

Two and a half years after diagnosis I returned to in the wards, and I soon qualified. I have since four years of house jobs of every sort. I do not equal to general practice, because if I have to be night I get too tired to carry on.

My day is usually as follows: Get up at 7.30 eat a good breakfast and travel to my clinic, I write letters till 10.30 A.M. and then see patients 1.30 P.M. An hour and a half for lunch, and then, acco to the day, I either see more patients or go to a t hospital for a ward round. I always rest, lying flat 5.30 to 6.45 P.M., usually reading a medical book, in the evening, after getting supper ready for I read or write until 11.

I can play three sets of tennis (doubles) or run for a I enjoy swimming, cycling, and walking. If I do to much I get overtired, and, knowing the symptoms, take grain of sodium phenobarbitone, which gives me a night's sleep. When my rest hour is due and I am aw from home I never hesitate to lie on the floor—th most restful place—even if I am in a strange househo Every winter I develop a cough with mucoid sp which I have examined regularly. I carry a piece toilet-paper in my pocket to spit into, and throw it the fire after use.

I go every six months to the chest physician who always seen me, taking my latest X-ray film and result (never more than 4 mm.). Sometimes if I a cold and have "tuberculophobia" I go to be rea What do I fear most? A positive sputum, an of reactivation; sometimes when depressed I I am getting a bronchopleural fistula, infection of other lung, and secondary infection of the empye necessitating rib-resection, thoracoplasty, and ultimate amyloid disease.

Two years ago I married the girl who, despite difficulties, visited me regularly from my diagnosis. spent our honeymoon walking in Switzerland, going up to 7000 feet and once to 11,000 on the funical That, I felt, was the supreme test of my fitness rehabilitation.

en towards the preparation and serving of food rink in this country just so long will it be difficult luence staffs by propaganda. In Switzerland and countries where this attitude does not exist there rs less cause for complaint.

W. S. Parker
Medical Officer of Health.
ıer.

—In his letter of Sept. 11 Dr. Stanley Turner attention to the need for improvement in the *ng* of food if the spread of disease is to be avoided. I suggest that there is also an urgent need for ved *inspection* of food in this country. and for closer oration between medical and veterinary authorities is subject? I hope that means will be found to available to your readers the paper which Mr. ıornton, chief veterinary officer of Newcastle-on- submitted to the 66th Annual Congress of my iation. This paper, and the discussion which ed, provided ample evidence of how far we lag l countries such as Denmark, the United States, ermany, in matters of food-inspection, and of the r to public health which results.

ats which arose during the discussion included: osence of antemortem veterinary inspection of ıls, especially "casualty cases," which so frequently ur salmonella organisms; (2) the existence in ıplaces of a knacker's yard alongside an abattoir; e release to sausage-makers of meat only safe for fter-sterilisation by heat; and (4) the sale at od shops of uncooked meat, sometimes from ulous carcases, subsequently handled by the aser and occasionally even bought with a view to n consumption.

SUPERNUMERARY NIPPLES

—May I draw attention to a condition which has been osed as a supernumerary nipple by two experienced al men? During hot weather about three years ago le patient of mine, then aged 65, developed an ary yellow-headed pimple over his right breast. was "squeezed" and a small amount of pus was ıated. He subsequently developed a small keloid t the size of a pea at the site. I watched this from eginning and there is no question about it. It is superficial, freely movable, has no deep attachs and no areola, and the skin over it is quite smooth nothing suggesting the opening of any ducts. re its appearance the skin was quite normal at the of the keloid, which is not pigmented.

okwood, Surrey. H. M. Stanley Turner.

TRAMEDULLARY NAILING OF FRACTURES

R,—My experience of the treatment of fractures by medullary nailing consists of only 3 cases, operated h 1940, but it does explain my reluctance to use the hod now. The idea of using a long trifin intrafullary nail for a fracture of the shaft of the femur urred to me in 1939 after I had been using the Smithersen trifin nail for fractures of the neck of the femur. er all, it is really only an extension of Smithersen's original method of fixation. Messrs. Down s made the nails for me; they were 15 inches long, n in cross-section, and of stainless steel. The cases hich they were used were transverse or short oblique tures of the middle third of the shaft of the femur.

he main details and difficulties encountered were ollows. The fracture was reduced, using an orthoic traction table, and a lateral incision was made e the greater trochanter, so as to expose the superior ct of that structure, from which a circular piece of was removed to give access to the medulla. The nail was introduced as far as the fracture line under y control and then the difficulties started. It was atial not only to make sure of an almost perfect ıction in both planes but also to ensure that the ments remained reduced while the nail was tapped ss the line of fracture. The screening this necessid was very considerable and dangerous to the ator if repeated at all frequently. The alternative of repeated films in two places was also very tedious and time-consuming. I did not attempt an open reduction of the fracture because this was the very procedure I was trying to avoid.

I understand that in the case of a fracture of the femoral shaft an open reduction is now usually employed; but if this is so, it is much simpler to plate the fracture. If plates with slots instead of round holes (Egger's type) are used, subsequent impaction is not prevented and all the advantages of intramedullary nailing are obtained through a single incision.

Norwich. G. K. McKee.

BINOCULAR MICROSCOPES

Sir,—I should like to thank Professor Hartridge for his letter of Sept. 11 in answer to mine of Aug. 14. He confirms that the real basis of eyestrain is interference with the normal muscle balance, and that this covers the imbalance of which I complain in converging-tube instruments, which compel convergence in spite of the fact that one's accommodation is relaxed. I notice, however, that he is scrupulously non-committal as to whether the microscopist does work with relaxed accommodation. I am satisfied that he does though the object always appears to be about ten inches away (presumably as a result of the association of ideas). An observation that seems to prove this is that, if you use a low-power ocular to examine objects with which you are familiar, they look much farther away than with your usual ocular. It is easy to see, therefore, why many people have jumped to the conclusion that they are accommodating. When working with a monocular instrument the unoccupied eye will be found to be focusing far beyond ten inches.

That the eyestrain produced by my converging-tube instrument is not produced by vertical displacement is readily verified by the method I always use for testing binocular instruments. The instrument is focused with one eye closed, and then the closed eye (which need not be the master eye) is rapidly winked. This does not give the normal muscle correction time to operate, and the displacement of the images is clearly apparent. I have a pair of binoculars in which this vertical displacement defies all my efforts to correct it, and I can entirely confirm Professor Hartridge's observations about the resulting eyestrain.

London, W.1. J. W. Shackle.

SPONTANEOUS RUPTURE OF THE RECTUM

Sir,—Mr. C. P. Allen's report (Sept. 4) prompts me to record a very similar case seen in this unit.

On the afternoon of Nov. 27, 1946, a man aged 47, who was manipulating a heavy brake lever in a shunting yard, felt a sudden pain in the rectum and lower abdomen. He had a desire to defæcate, but was unable to do so. Next day he passed a normal motion, but the abdominal pain grew worse, and on Nov. 29 he was admitted to hospital.

He was now in great pain and was dyspnœic. Temperature 98°, pulse 100, poor volume. The abdomen exhibited poor respiratory movements, board-like rigidity, and absence of peristaltic sounds. Rectal examination revealed tenderness high up but no other abnormal finding. Laparotomy was carried out and turbid fluid escaped. The pelvic colon was found to be adherent about a large collection of solid fæces lying free in the peritoneal cavity. An oblique rent 2 in. long was found in the anterior wall at the pelvirectal junction. The descending colon was loaded with fæces. The rent was closed, the abdomen closed without drainage, and a left inguinal colostomy carried out. The patient made a good recovery; the colostomy was closed on May 7, 1947, and he is now fit and well.

The striking features of our case are the length of time between the rupture of the rectum and the patient's admission to hospital, and the fact that the peritoneal cavity had made an almost successful attempt to seal off the escaping fæces; no fæcal odour was noticed until the adherent loops of bowel were gently separated. As Mr. Allen says, the condition may not be as rare as has been supposed.

Letters to the Editor

M.R.C.P. EXAMINATION

SIR,—The M.R.C.P. examination has often been subjected to criticism, not only by rejected candidates but also by the comitia of the Royal College of Physicians. The organisation of the whole examination will no doubt be carefully reviewed in the near future. Any views which I express here are personal and not official.

I was Senior Censor in 1942–43 when the entries were approaching 200. Although this is far short of the present hordes, the problems arising were similar.

Two questions which appear in the recent letters have been repeatedly discussed—viz., the requirement before entry of certain resident appointments or of a minimal interval after qualification, and the length of the clinical examination.

Before the late war, the requirement of resident appointments would probably have had little influence on the number of entries, since nearly all candidates could have complied with it. It might involve some difficulties with candidates from overseas, and possibly at the present time with those from the Services, but these could be overcome. There does not appear to be any valid permanent objection, and there are arguments in its favour, apart from any effect on the number of entries.

The length of the clinical examination has caused much anxiety. The arrangements for holding this examination, even at its present length, involve a serious burden on the hospitals to which the Censors are attached. This burden falls especially heavily on the registrars. The necessary preparations are now so time-consuming as to interfere definitely with their normal duties. Unless the entries can be materially reduced it would be difficult appreciably to increase the length of the clinical examination.

The question of reducing the number of entries by some fair method merits study for this and other reasons. The aim would be to discourage the weaker group and the candidate who "has a go at it."

The rapid elimination of candidates after entry also presents difficulties. No trivial test would be satisfactory. "M.R.C.P." suggests that 60% should be eliminated by "stiff papers." This method would introduce a competitive factor which has always been carefully avoided. Further, by throwing the emphasis on a written examination, it would defeat "M.R.C.P.'s" object of a more critical clinical examination. It would almost ask for freak questions, which are the worst possible criteria. Elimination by the clinical examination is more in accordance with the tradition of the membership.

It should be borne in mind that reading membership papers is very exhausting. For a qualifying examination 8 or 10 papers per hour can be assessed, and the strain is slight. Few examiners can mark more than 4 an hour for the membership.

The theme that success in the examination depends on luck runs through many of the letters. I do not believe that there is more luck in the membership than in other comparable examinations. It is frequently asserted that men who pass after many attempts, or even consistently fail, are as good as those who get through without difficulty. This statement is undoubtedly incorrect. The evidence is that the good man gets through and the weak man fails, though anybody may fail once. In view of the high percentage of rejections it is striking how many candidates pass at their first or second attempt, and it is these men who supply the great majority of the future leaders of the profession. Shortly after the first war I was told the names of the four men who had earned outstanding marks in the previous 4 or 5 years, and I have remembered them. All four now have international reputations.

Candidates here as elsewhere can be divided into three groups. The first group is above the borderline area, and can take a piece of bad luck and pass in spite of it. Indeed if bad luck is represented by an obscure neurological case, as seems to be almost universally accepted, the good man may profit by it.

The second group is below the borderline are rarely rises into it. Success of a member of this may be attributed to a fluke rather than to ord luck.

The third group is in the borderline area, and wo exasperatingly above and below the pass line. It the despair of the conscientious examiner. A viva of 60 minutes and a clinical examination lasting all would leave the examiner still in doubt, for this is intellectually and permanently on the line. A of good luck may put up a man sufficiently to pas (as one letter-writer states) he is no better than he was ploughed. A man from this group may ce achieve success in after-life exceeding that of m his contemporaries in the first group; but usually t the result of personality and bedside manner than professional ability.

The pertinent question has been asked as to w the significance of the examination. This has been formulated and depends on tradition, for t are no rules limiting or directing the Censors.

The examination essentially demands a high stan both theoretical and practical, in the basic prin of medicine. It may well happen that a candida not asked a single question or given a clinical case he could not equally and fairly have encountered qualifying examination. And yet he may fail. examiner in a final examination often gives a candi a second chance. He will say "Think again, Do you really mean that?" It is most unlikely that will be heard in the membership. In the routine method of examining a patient, and in the recogni and evaluation of obvious physical signs, the candi must be right the first time.

It is here that many a candidate goes astray. Inst of studying over and over again one of the books physical diagnosis, and making certain that in the the methods laid down are conscientiously follo until they become ingrained as an *automatic* rou many assume that their knowledge and practice is a complete up to this stage, and that they are free to to more advanced branches of medicine. And so fail repeatedly at simple cases, not because the exa is pernickety but because they are unaware and re unaware of their own shortcomings. The succe a fellow-student of no greater abilities but who laid his foundations more surely only leaves them than ever convinced that the examination depend luck.

Thus the membership attests that a successful cand has an assured knowledge of the general principl medicine and is intellectually fitted to advance from point by any one of many paths which he may select himself, and it is on this basis that the membership attained its present status.

London, W.1. HENRY TIDY.

HANDLING OF FOOD

SIR,—The deplorable methods of handling food mentioned by Dr. Stanley Turner in his letter of Sept. 11 will be regretted by all. The problem is complicat by the variety of premises and the equipment which is reasonable for them to instal for the special nee of their branch of catering.

I have yet to hear of any great effort to improv licensed premises in this respect. The minimum nee is for the use of twin sinks for washing up, in order permit the use of a detergent and for rinsing. addition, the number of glasses should bear some relatio to the expected peak rush of customers. False economy in the use of water charged by meter is an addition factor.

Elementary methods of food hygiene can only be taught in surroundings which are maintained at suitable standard. We hope to initiate this here in the coming winter by remodelling of municipal caterin premises, using existing materials as far as possible, that when the pier restaurant and the like are le to catering contractors these can be demonstrated to hoteliers and their staffs and provide a standard fo private catering establishments.

Catering staffs vary in their training, but all ar looked down on. As long as a slightly shameful approac ation often only the granules and the nucleus are . In such a cell, although the granules are still within toplasmic boundary the stained appearances suggest hey have lost all contact with the cell. Such a cell n intensely active and may some minutes later be again d up into its classical shape.

ŒSTROGEN AND BLOOD-SUGAR

SIR,—It may be of interest to other workers if I place on record my observation that patients treated with diethylstilbœstrol in oral doses of 5 mg. daily for 2–3 weeks have developed symptoms of hypoglycæmia.

Jerusalem. GEORGE BIRO.

MEDICAL RECORDS

SIR,—There is one difficulty on which "Medical Superintendent" in his interesting letter (Sept. 4) did not touch: given a secretary with the necessary qualifications and a physician or surgeon who requires her services, how do they find each other? I have been disengaged for some months and have not yet heard of a medical post I should like. There are numerous secretarial posts, but I have a predilection, regarded by my friends as slightly pathological, for medical work. One can, of course, advertise in the local press, or one could look up one's former employers or acquaintances influential in medical rectangles. The first method is slow and unproductive; the second doesn't appeal to me. Surely there is room for some sort of organised liaison between doctors and secretaries?

EUCILIUS.

PRIMARY TUBERCULOSIS WITH MENINGISM

Professor Choremis informs us that in both of the cases reported in his paper of Sept. 11 (p. 408) the children are in good health, with no signs of relapse or of development of disease, 9 months and 6 months respectively after the onset of their illness. Since his paper was written routine examination of the cerebrospinal fluid in similar cases has revealed three more children showing tubercle bacilli in the fluid on culture without any symptoms of meningitis.

Public Health

Deadly Nightshade Poisoning

IN addition to the five cases of belladonna poisoning reported from Portsmouth in our issue of Sept. 11 (p. 438), two further cases have since been treated at the Royal West Sussex Hospital, Chichester. Dr. G. T. Rutherfoord reports that at 11 P.M. on Sept. 7 two sisters, aged 5 and 3½ years, were admitted to the hospital under the care of Dr. H. Seaward Morley with the diagnosis of acute belladonna poisoning. Between 2 and 2.30 P.M. on that day the children had been playing on a bombed site where they had eaten berries. At about 4.30 P.M. they had asked for buns, but were unable to eat them owing to dryness of the mouth. They refused a drink of water and were noticed to be hoarse. They were put to bed and slept from 5 to 7 P.M. when the younger child awoke and behaved strangely, and later brought up some brown vomit. Medical advice was sought, and she, together with her elder sister who also appeared unwell, were sent to hospital, the younger again vomiting before arrival.

On admission to hospital the younger child was fully conscious, though strange in her manner; her mouth was dry. The elder was semiconscious, and her mouth was not obviously dry. Apart from these points the physical signs in each were similar: the pupils were widely dilated and there were rapidly recurring jerky movements of the limbs. Gastric lavage was performed immediately. The washings were brown, and contained partly digested food, the only recognisable constituent of which was a quantity of plum skins, which had been taken at the midday meal. After the lavage a saline aperient was given.

During the first 12 hours after admission the children were very restless in spite of sedation. Thirst was conspicuously absent. Between 12 and 24 hours after admission they were delirious with hallucinations. After 24 hours there was gradual improvement until the 3rd day, when both children appeared perfectly well and happy, though their pupils were still widely dilated. A moderate degree of tachycardia (120–130 per min.) and pyrexia (99–100°F), which had persisted since admission, had by then disappeared.

BLOOD FOR TRANSFUSION

SIR,—The paper by Dr. Piney in your issue of Sept. 4 appeared to indicate dissatisfaction with the service provided by the National Blood Transfusion Service.

One of us (K. S. T.) when working at Colchester made many calls on this service, and Mr. Blaxhill was most helpful, providing on a number of occasions from 10 to 27 pints for any one patient. More recently we have treated a case of acute leukæmia here by exsanguinotransfusion, and Dr. W. Weiner, the regional transfusion officer, provided us with 36 pints of specially matched blood.

Not only are we satisfied with the supply of blood, but we would express the opinion that the serological work of the regional transfusion officer is of a much higher standard than can be expected of all but a very few pathologists.

W. P. U. JACKSON
Birmingham. K. S. THOMPSON.

SIR,—It will, I think, be generally agreed that even in the larger hospitals a temporary shortage of blood occurs from time to time, and that in many smaller ones the shortage is ever present. Discretion is therefore necessary in the use of blood for transfusion so that waste may be avoided.

Dr. Maycock defends the transfusion centres whose average good service needs no defence, and in arguing the defence, explains some of the shortage by accepting its existence.

It is true that there may be a relative deficiency of the rarer AB and B donors, and an even greater deficiency of AB and B donors who are also Rh-negative; but the rarity of AB and B donors parallels the rarity of the AB and B patients, and therefore an adequate donor service should prevent a deficiency.

It is over the methods required to provide such a service that I disagree with Dr. Piney. The provision of chits to enable donors to purchase extra rations would cease to be effective if and when rationing ends, and would then have to be replaced by a cash equivalent; moreover the reward would have to be disproportionately high in order to tempt a large enough number of people; for, as a race, we seem to react only to critical danger or great personal reward. It is for the same reason that I think good publicity can be only the adjuvant in the remedial mixture.

In my experience a solution may be found with junior house-officers in coöperation with the pathology department. If it becomes the regular practice for the house-man to interview relatives of patients who require transfusion, and explain in simple terms the maintenance of the hospital blood "bank account" and the necessity for special tests on the blood, it will be found that in most cases the relatives are willing to have their names placed on the donor panel to replace the blood when called upon to do so, and that the majority of these do in fact attend when asked. Moreover, after attending once they are usually willing to come again, and blood may thus be replaced in the ratio of 3 : 1 or more. The nucleus of a panel thus formed can be added to by volunteers, hypertensives, and others as opportunity offers.

This is, I feel sure, the key to the situation. Once such a practice had become commonplace, the replacement by relatives of blood transfused to patients would become an accepted routine, and the difficult problem of rewards, financial or other, need never arise.

The organisation of the collection and testing of blood must, for obvious reasons, be subject to local conditions: wherever possible the facilities of the regional transfusion centres should be used, but until these are sufficient it is possible to organise "local" transfusion services in conjunction with the pathology departments. Their success depends upon the active interest of all the staff, irrespective of seniority, and upon attention to detail in the matters of tact, courtesy, cups of tea, letters of thanks, and so on, all of which give rich dividends on the time invested.

Apathy is fatal, and especially to be avoided is such an apathetic manœuvre as the conferment on a junior resident of the placebo title of "transfusion officer," with duties so nebulous that they cannot be enforced, or the adoption of the complacent attitude that one alone and without the wholehearted aid of his coll can maintain a donor service.

R. D. POPHA
Assistant Pathologist.

INTERNATIONAL CONGRESS ON POPULATI

SIR,—Some mistakes seem to have crept into report of Sept. 4 on the Cheltenham congress on tion. The German birth-rate in 1933 was not Dr. Durand-Wever is supposed to have said), 8 1000, but 14·7. "At the height of the Hitler ganda" (1939) it rose to 20·3, not to 14·9. The rate in Germany was not 5·8 per 1000 in 1938 but No country in the world knows of such a low dea as 5·8. The Czechoslovak speaker can scarcely said that there has been a "steady increase in the rate of his country since the 1914–18 war," for the opposite happens to be the fact. In accordance the general European trend, the Czechoslovak birt declined steadily between 1920 and 1938, from to 16·8. That the practice of contraception "has found much support" in that country is not by the facts. Every government aims at the "red of illegal abortions," but I have never heard of any measure taken by the Czechoslovak government in direction.

JOSEPHINE BRU
Plaistow Fever Hospital, London, E.13.

*** We are obliged to Dr. Bruegel for drawing atte to these discrepancies. Nevertheless the figures attributed to Dr. Durand-Wever tally with those of official report, and we hope to be able to confirm the Czechoslovakian delegate made the state ascribed to him.—ED. L.

THE EOSINOPHIL CELL

SIR,—I was interested in Dr. Duran-Jorda's of Sept. 18. During studies of the eosinophil cell stained and in its live state, extending over ten I have observed various activities which may interest in connexion with his theory of the ori red blood-corpuscles, though they do not sup theory.

(1) The human eosinophil may contain spherical or it may contain cubical or even oblong box-like g I have not seen ovoid granules, but they are by no always spherical.

(2) Both eosinophils and neutrophils in certain pha activity produce vesicles on their surfaces which ten become separated from the cell and float away free in surrounding medium. These vesicles vary in size from to about 7 μ and often consist of cytoplasmic material w granules. Such vesicles or corpuscles may be very ab in pathological material such as sputum or thin pus and quite common in urine. Those produced by the neu are very difficult to see under the microscope in the uns preparation, but those produced by the eosinophil are readily visible owing to their higher refringence and very readily be mistaken for a red blood-corpuscle when size is comparable.

(3) Often before becoming detached from the neutrophil or eosinophil such vesicles or corpuscle receive a certain number of granules, and such gra containing vesicles are often encountered floating loose the parent cell. This type of vesicle has been observed perform phagocytosis, although it contains no nucleus size of the vesicle bears no relation to its granular cont quite small vesicles often abounding in granules

(4) Both the eosinophil and the neutrophil cell r extrude long filopodia with which they perform prodigi phagocytosis and which can be seen enwrapping shed epit cells in pathological fluids. At no time have I seen perform phagocytosis of red blood-corpuscles in such mat

(5) It is clear from the above remarks that the free-fl corpuscles are not derived from granules, so that they not qualify for erythropoiesis by the method suggested Dr. Duran-Jorda.

(6) When the eosinophil cell is indulging in filop activity it may extrude the granules in the filopodium distance of over 100 μ from the nucleus. In the st

ion often only the granules and the nucleus are In such a cell, although the granules are still within plasmic boundary the stained appearances suggest y have lost all contact with the cell. Such a cell ntensely active and may some minutes later be again up into its classical shape.

bove activities of neutrophils and eosinophils scribed and illustrated along with certain others aper[1] five years ago.

Sir,—There is one difficulty on which "Medical Superintendent" in his interesting letter (Sept. 4) did not touch: given a secretary with the necessary qualifications and a physician or surgeon who requires her services, how do they find each other? I have been disengaged for some months and have not yet heard of a medical post I should like. There are numerous secretarial posts, but I have a predilection, regarded by my friends as slightly pathological, for medical work. One can, of course, advertise in the local press, or one could look up one's former employers or acquaintances influential in medical rectangles. The first method is slow and unproductive; the second doesn't appeal to me. Surely there is room for some sort of organised liaison between doctors and secretaries?

Euchius.

PRIMARY TUBERCULOSIS WITH MENINGISM

Professor Choremis informs us that in both of the cases reported in his paper of Sept. 11 (p. 408) the children are in good health, with no signs of relapse or of development of disease, 9 months and 6 months respectively after the onset of their illness. Since his paper was written routine examination of the cerebrospinal fluid in similar cases has revealed three more children showing tubercle bacilli in the fluid on culture without any symptoms of meningitis.

Public Health

Deadly Nightshade Poisoning

In addition to the five cases of belladonna poisoning reported from Portsmouth in our issue of Sept. 11 (p. 438), two further cases have since been treated at the Royal West Sussex Hospital, Chichester. Dr. G. T. Rutherfoord reports that at 11 P.M. on Sept. 7 two sisters, aged 5 and $3^1/_2$ years, were admitted to the hospital under the care of Dr. H. Seaward Morley with the diagnosis of acute belladonna poisoning. Between 2 and 2.30 P.M. on that day the children had been playing on a bombed site where they had eaten berries. At about 4.30 P.M. they had asked for buns, but were unable to eat them owing to dryness of the mouth. They refused a drink of water and were noticed to be hoarse. They were put to bed and slept from 5 to 7 P.M. when the younger child awoke and behaved strangely, and later brought up some brown vomit. Medical advice was sought, and she, together with her elder sister who also appeared unwell, were sent to hospital, the younger again vomiting before arrival.

On admission to hospital the younger child was fully conscious, though strange in her manner; her mouth was dry. The elder was semiconscious, and her mouth was not obviously dry. Apart from these points the physical signs in each were similar: the pupils were widely dilated and there were rapidly recurring jerky movements of the limbs. Gastric lavage was performed immediately. The washings were brown, and contained partly digested food, the only recognisable constituent of which was a quantity of plum skins, which had been taken at the midday meal. After the lavage a saline aperient was given.

During the first 12 hours after admission the children were very restless in spite of sedation. Thirst was conspicuously absent. Between 12 and 24 hours after admission they were delirious with hallucinations. After 24 hours there was gradual improvement until the 3rd day, when both children appeared perfectly well and happy, though their pupils were still widely dilated. A moderate degree of tachycardia (120–130 per min.) and pyrexia (99–100°F), which had persisted since admission, had by then disappeared.

BLOOD FOR TRANSFUSION

SIR,—The paper by Dr. Piney in your issue of Sept. 4 appeared to indicate dissatisfaction with the service provided by the National Blood Transfusion Service.

One of us (K. S. T.) when working at Colchester made many calls on this service, and Mr. Blaxhill was most helpful, providing on a number of occasions from 10 to 27 pints for any one patient. More recently we have treated a case of acute leukæmia here by exsanguino-transfusion, and Dr. W. Weiner, the regional transfusion officer, provided us with 36 pints of specially matched blood.

Not only are we satisfied with the supply of blood, but we would express the opinion that the serological work of the regional transfusion officer is of a much higher standard than can be expected of all but a very few pathologists.

W. P. U. JACKSON
K. S. THOMPSON.

Birmingham.

SIR,—It will, I think, be generally agreed that even in the larger hospitals a temporary shortage of blood occurs from time to time, and that in many smaller ones the shortage is ever present. Discretion is therefore necessary in the use of blood for transfusion so that waste may be avoided.

Dr. Maycock defends the transfusion centres whose average good service needs no defence, and in arguing the defence, explains some of the shortage by accepting its existence.

It is true that there may be a relative deficiency of the rarer AB and B donors, and an even greater deficiency of AB and B donors who are also Rh-negative; but the rarity of AB and B donors parallels the rarity of the AB and B patients, and therefore an adequate donor service should prevent a deficiency.

It is over the methods required to provide such a service that I disagree with Dr. Piney. The provision of chits to enable donors to purchase extra rations would cease to be effective if and when rationing ends, and would then have to be replaced by a cash equivalent; moreover the reward would have to be disproportionately high in order to tempt a large enough number of people; for, as a race, we seem to react only to critical danger or great personal reward. It is for the same reason that I think good publicity can be only the adjuvant in the remedial mixture.

In my experience a solution may be found with junior house-officers in coöperation with the pathology department. If it becomes the regular practice for the house-man to interview relatives of patients who require transfusion, and explain in simple terms the maintenance of the hospital blood "bank account" and the necessity for special tests on the blood, it will be found that in most cases the relatives are willing to have their names placed on the donor panel to replace the blood when called upon to do so, and that the majority of these do in fact attend when asked. Moreover, after attending once they are usually willing to come again, and blood may thus be replaced in the ratio of 3 : 1 or more. The nucleus of a panel thus formed can be added to by volunteers, hypertensives, and others as opportunity offers.

This is, I feel sure, the key to the situation. Once such a practice had become commonplace, the replacement by relatives of blood transfused to patients would become an accepted routine, and the difficult problem of rewards, financial or other, need never arise.

The organisation of the collection and testing of blood must, for obvious reasons, be subject to local conditions: wherever possible the facilities of the regional transfusion centres should be used, but until these are sufficient it is possible to organise "local" transfusion services in conjunction with the pathology departments. Their success depends upon the active interest of all the staff, irrespective of seniority, and upon attention to detail in the matters of tact, courtesy, cups of tea, letters of thanks, and so on, all of which give rich dividends on the time invested.

Apathy is fatal, and especially to be avoided is such an apathetic manœuvre as the conferment on a junior resident of the placebo title of "transfusion officer," with duties so nebulous that they cannot be enforced, or the adoption of the complacent attitude that alone and without the wholehearted aid of his can maintain a donor service.

INTERNATIONAL CONGRESS ON POPU

SIR,—Some mistakes seem to have crept into report of Sept. 4 on the Cheltenham congress on tion. The German birth-rate in 1933 was not Dr. Durand-Wever is supposed to have said), 8·7 1000, but 14·7. "At the height of the Hitler ganda" (1939) it rose to 20·3, not to 14·9. The rate in Germany was not 5·8 per 1000 in 1938 but No country in the world knows of such a low as 5·8. The Czechoslovak speaker can scarcely said that there has been a "steady increase in the rate of his country since the 1914–18 war," for the opposite happens to be the fact. In the general European trend, the Czechoslovak declined steadily between 1920 and 1938, from to 16·8. That the practice of contraception found much support" in that country is not by the facts. Every government aims at the of illegal abortions," but I have never heard of measure taken by the Czechoslovak government direction.

JOSEPHINE

Plaistow Fever Hospital, London, E.13.

*** We are obliged to Dr. Bruegel for drawing att to these discrepancies. Nevertheless the figures attributed to Dr. Durand-Wever tally with the official report, and we hope to be able to confirm the Czechoslovakian delegate made the stat ascribed to him.—ED. L.

THE EOSINOPHIL CELL

SIR,—I was interested in Dr. Duran-Jorda's of Sept. 18. During studies of the eosinophil cell, stained and in its live state, extending over ten I have observed various activities which may interest in connexion with his theory of the red blood-corpuscles, though they do not theory.

(1) The human eosinophil may contain spherical or it may contain cubical or even oblong box-like I have not seen ovoid granules, but they are by always spherical.

(2) Both eosinophils and neutrophils in certain activity produce vesicles on their surfaces which become separated from the cell and float away free surrounding medium. These vesicles vary in size from to about 7 μ and often consist of cytoplasmic material granules. Such vesicles or corpuscles may be very in pathological material such as sputum or thin pus quite common in urine. Those produced by the neu are very difficult to see under the microscope in the preparation, but those produced by the eosinophil are readily visible owing to their higher refringence and very readily be mistaken for a red blood-corpuscle when size is comparable.

(3) Often before becoming detached from the neutrophil or eosinophil such vesicles or corpuscles receive a certain number of granules, and such containing vesicles are often encountered floating loose the parent cell. This type of vesicle has been obs perform phagocytosis, although it contains no nucleus. size of the vesicle bears no relation to its granular quite small vesicles often abounding in granules.

(4) Both the eosinophil and the neutrophil cell extrude long filopodia with which they perform prod phagocytosis and which can be seen enwrapping shed cells in pathological fluids. At no time have I seen perform phagocytosis of red blood-corpuscles in such ma

(5) It is clear from the above remarks that the free-f corpuscles are not derived from granules, so that they not qualify for erythropoiesis by the method suggested Dr. Duran-Jorda.

(6) When the eosinophil cell is indulging in fil activity it may extrude the granules in the filopodium distance of over 100 μ from the nucleus. In the st

ɔers of the increased millions of the world were rfed. Before the war there were millions of people is country underfed, and now, badly off as we were. ɔd many were better fed than before, especially the ren. The Government would like a lot more to be r fed. He protested against the suggestion that the ase of production from our land meant a diversion our manufacturing efforts, but the Government quite ready to accept Lord De La Warr's motion.

Notes and News

NATIONAL HEALTH SERVICE

MR. BEVAN REVIEWS THE SITUATION

SPEAKING at the annual dinner of the Society of Medical Officers of Health, held in London on Sept. 16, Mr. ANEURIN BEVAN, Minister of Health, said that controversy over the National Health Service Act had been inevitable, but he now looked forward to a period of fruitful collaboration in one of the greatest enterprises ever undertaken by an administration in peace-time. The transition had so far gone with unexpected smoothness, thanks largely to the efficiency of the Civil Service. The object was to secure coöperation, for the benefit of the public and the advancement of medical science, between the State financial machine and the voluntary workers who (though foreigners could not believe it) administered the service. The national genius was to get hold of a principle of this sort "and warm it up by the enterprise of ordinary men and women." No doubt many defects would be revealed and call for improvising ability. He had been much afraid that the middle and professional classes (for whom illness was often especially harassing) might be persuaded to stay outside the service, by people who told them that it was for the needy. But the danger of "a schizophrenic service" had almost passed. The last figures showed that 92–93% of the population had already signed up, and new signatures were coming in at the rate of 150,000 a week. It looked as though nearly everybody would be included by the end of the year, and he was delighted at this because it meant that the N.H.S. would be a classless service. It had been fully expected that during the first year there would be a rush for many of the facilities provided. The natural desire to get something for nothing would wear off; but the new demand was also largely due to real needs which people previously could not afford to meet: it was surprising, for example, to find how many old-age pensioners had been buying their spectacles at Woolworth's. Dentists were now coming into the service more quickly, and no doubt as time went on most of them would be in the scheme.

Many had feared (*Mr. Bevan continued*) *that the Act would* produce a split between different parts of the service: and on the surface it had looked as though they were justified. But he had always believed that the medical officer of health would join up what would otherwise be disjointed: and in fact M.O.H.s had done magnificent work of this kind in the past year. He was very keen on health centres, and was anxious that some should be built quickly. "But we're trying to do an awful lot of things at once." If he had to choose between the preventive effects of a good new house and the curative effects of a new health centre he would choose the house: enough new houses would diminish the need for health centres. Important though the therapeutic contribution to health was, the silent contribution of preventive medicine was far greater —made through such things as a pure piped water-supply, building regulations, sanitary inspection, and the Acts governing food and drugs. He hoped that the M.O.H. would continue to serve as a unifying principle in the health service.

Dr. FREDERICK HALL, president of the society, was glad to think of the M.O.H. as a bridge between preventive and curative medicine: but some bridges were temporary, some were swept away, and some were preserved merely as ancient monuments. He hoped this particular one would be given strong support and firm foundations, part of the support being financial. The Act would be very difficult to operate unless all possible *means were used to limit the incidence of disease*—which was not being done at present. In replying to Dr. J. GREENWOOD WILSON's toast of The Guests, Dr. GUY DAIN, chairman of the council of the British Medical Association, said that the terms of service for different branches of the profession must be so integrated that no branch offered outstanding financial attractions. The association and (he was sure) all doctors would do their best to see that the service was a success, though they would point out defects as these occurred. The Minister had solidified the profession in a way never thought possible and he should make good use of its unity. The best results would come from the service if its members were well organised and well able to express their views. Sir WYNNE CEMLYN-JONES also responded.

It was impossible to be certain how many berries had been eaten, but the elder child stated that both she and her sister had taken one berry each. A plant taken from the place where the children had been playing was found to be *Atropa belladonna* (deadly nightshade).

Typhoid Fever on Clydeside

In the outbreak of typhoid fever in the Greenock, Port Glasgow, and Gourock areas of Clydeside, referred to *on p. 471 last* week, further investigation in Kilcreggan among people living beside the stream has revealed the presence of a carrier. This person, aged 80, had had typhoid fever at the age of 27 and had remained well since then. More accurate typing of the organism isolated from the numerous cases and from the carrier has shown that the type (F2) is an unusual one. One more case has occurred in Gourock associated with this stream; this is in a girl of 6 years who appears to have been ill at home for some time before the family doctor was called. One or two cases in this household are also under observation, and from the dates of sickening these are more likely to have arisen from the girl than from primary infection at the stream, though they too had taken part in picnics and had drunk water from the stream.

Parliament

A Short Session

A SPECIAL session of Parliament was opened by the King on Sept. 14 to pass for the second time through the House of Commons, before it goes once more to the House of Lords, the Parliament Bill which proposes to limit the power of the Lords to hold up legislation to a period of one year. As this measure is the only legislative business of the session the King's Speech was unusually short—74 words—but occasion was taken in the House of Commons in the debate on the Address to discuss matters of national and international interest.

Defence Measures

Mr. HERBERT MORRISON, Lord President of the Council, in his speech, for instance, made an important announcement on defence. All National Service men, he stated, due for release in the next few months who had not left their units by Sept. 14 must be retained for three months beyond the date on which they would normally have been released. In this way alone could the loss of trained men be halted. Releases in class B and on compassionate grounds would not be affected. This change would increase the strength of the Armed Forces by about 80,000. Mr. Morrison emphasised that the increase was in trained men who constituted the real need.

Mr. Morrison also assured the House that considerable progress had already been made with plans for assisting the population, for the reorganisation of the civil-defence services, and for the preparation of any legislation that might be necessary. While the measures which the Government were taking would have some effect upon our economy, it was hoped they would not jeopardise our recovery.

The Farm and the Factory

In the House of Lords on Sept. 16 Earl DE LA WARR moved:

> That this House is of opinion that plentiful food imports are not likely to be available in the foreseeable future, and that it is desirable that the emphasis of our Empire and national economic policy and the allocation of capital resources and man-power should be adjusted to meet this change in our circumstances.

So long as economists advised governments, he continued, that in the reasonably near future there was still a possibility of our being able to return to the good old days of dear exports in exchange for cheap imports of food and raw materials it was unlikely that any government would tackle the problem of making the most of our own soil and our own Empire. The Emergency Food Council's estimate that world production of grain would equal pre-war supplies assumed good harvests, 60% now came from America and Canada, Lord Warr pointed out, we were therefore dependent on weather in that hemisphere. Again, before th 6 million tons of fats and oils were available for this year it was hoped to reach 4 million tons. exports in 1948 were expected to be 40% above t 1947, but, even so, they would be only 40% of the war figure. The Emergency Food Council's figures showed a reduction of 10–15% in the production o

Lord De La Warr was further disquieted to great food producing countries increasing indu at the expense of agriculture. Their populations increasing, and they were tending to keep more themselves, and also making it more difficult for sell our exports. Where were our economists when they warned us against the danger of a too many of our resources to the development of own soil? He recognised that to implement his would mean refocusing our national economic o but it was, he held, a national approach to a problem fundamental to our very existence.

The Earl of HUNTINGDON, joint parliamentary tary to the Ministry of Agriculture, did not doubt danger of the situation, but he urged their Lord take a balanced view. We were not likely to anything like all the food we needed in these the problem therefore arose as to how we were to our food imports. If we were going to have so smoke and a reasonable cut from the Sunday could only get them by our own efforts and He could see no good reason why this nation produce an abundance of the services and other needed to pay for our imports. A more difficult was whether other countries could pay for our in sufficient volume to enable us to buy in Population was undoubtedly increasing, but added, was the scope for improvement of production. The Government recognised that the main and first essential and from the start devoted much of their energies to encouraging production in this country, in the Common Colonies and elsewhere overseas.

Viscount BRUCE of MELBOURNE thought that fo years we must act on the basis of sheer necessity quite apart from any question of balance of pa external payments or anything else. Britain would to achieve and remain on a much higher level of tural production than formerly.

Lord BEVERIDGE suggested that making the a bad job had become one of our major industr that the debate fell within the scope of that He believed that the long-term trend which thro the 19th century had made our position better and through our exchanging industrial products had reversed and would continue to be reversed. But we recognise the price of turning this country over man more to agriculture from industry. There was a sl of man-power, and if we had to grow a great deal of ourselves we should have fewer houses and other th we need. We must therefore take care not to dev agriculture unless it meant that we could get our food home production more cheaply in terms of labour t we could get it by exchange from abroad. Agric must prevail on its own merits, because we needed it, not by protection. He agreed, however, that we bound to make agriculture both more productive man and more attractive of men in relation to indu than it was at present. He also stressed that should be made to realise that our relatively prosperity had gone for ever.

Ending the debate Viscount ADDISON, Lord Pr Seal, said that according to our present progra which seemed likely to be attainable, we aimed at tonnage of bread grains of 2,750,000 tons, and a po yield of 7,250,000 tons. It was obvious, he said, more food must be produced in the sterling ar long-term contracts, leading it was hoped to incr production, had already been made with colonial c tries for wheat and flour, dairy products, meat and b eggs, vegetable oils, sugar, dried fruits, and coffee.

It was true that there was a world scarcity, th there might be here and there a successful harvest.

PENICILLIN IN DIPHTHERIA

RT OF A SUBCOMMITTEE OF THE PUBLIC HEALTH LABORATORY SERVICE*

is investigation the penicillin-sensitivity of 284 of *C. diphtheriæ* isolated in different parts of the was measured. An attempt was also made to t if penicillin treatment shortened the time of of *C. diphtheriæ* in acute cases of faucial diph- nd eliminated the organism in persistent throat . Information on the clinical effect of penicillin s of diphtheria was not sought. Though there is agreement that *C. diphtheriæ* is sensitive to in in laboratory tests, the evidence for this view rests on separate reports on a few strains (Long This criticism also applies to much of the work penicillin treatment of acute cases and chronic , though Karelitz et al. (1947) have treated te cases of diphtheria with encouraging results. e of the low incidence of diphtheria in this we tried to secure sufficient material for nation by carrying out our tests in eight tory areas.†

SENSITIVITY OF STRAINS TO PENICILLIN

hnique.—A standarised and stabilised penicillin on was distributed every fortnight by Dr. Joseph r, of Glaxo Laboratories Ltd., and this was used ll tests. The requisite amount of penicillin was l in bulk to nutrient broth (pH 7·5) which contained Lab Lemco,' 1% proteose peptone, 0·5% sodium ide, and 5% of a single batch of heat-inactivated -filtered horse serum : 5 ml. of this broth was used ach dilution of penicillin, which ranged from 0·6 ·03 unit per ml. of medium. For each strain of *iphtheriæ*, therefore, six tubes containing penicillin inoculated together with a broth tube without cillin. In addition a similar control series of tubes ulated with the Oxford staphylococcus accompanied strain under test, and when a batch of strains was d it was customary to put up controls inoculated stock strains of the three types of *C. diphtheriæ*.

ch tube was inoculated with an arbitrary standard ful ('Nichrome'-wire loop of internal diameter n.) of an overnight culture of the organism grown e broth medium. Tubes were then incubated at for twenty-four hours. After thorough shaking the s were examined and the turbidity was recorded. the tube at the visual end-point and from the containing the next highest concentration of illin a standard loopful was then spread on half a blood-agar plate. The number of colonies developing after overnight incubation was estimated and compared with the number obtained from a control tube. This control, with which it was intended to estimate the size of the original inoculum, was prepared by adding a standard loopful of an overnight broth-culture of the strain under test to 5 ml. of the broth medium, and plating out immediately. Subcultures from tubes yielding numbers of colonies greater than half the number from the control were, for the purposes of the test, considered not to show inhibition ; the first tube from which subculture gave less than half the number of colonies from the control tube indicated the penicillin sensitivity of the strain.

Results.—Most of the strains were tested in each of two laboratories, and only very occasionally was there more than a one-tube difference in the sensitivities recorded. Such differences were observed with twelve strains, and these were retested before they were recorded. Under the conditions of our tests the Oxford staphylococcus was inhibited by 0·1 unit of penicillin per ml. of medium. This relatively high reading may be associated with the size of the inoculum used in our tests ; with 1/500 of this inoculum the reading was 0·05 unit per ml. In two small batches of strains of *C. diphtheriæ* tested in two different laboratories where the bacteriostatic levels for the strains of *C. diphtheriæ* were above the average the Oxford staphylococcus was inhibited by 0·2 unit of penicillin, but the ratio was normal. Though it is necessary to mention these few discrepant results, the findings in the different laboratories were remarkably uniform. The results (tables I and II) show that gravis strains of *C. diphtheriæ* are rather more resistant to penicillin than intermedius, and that intermedius are more resistant than mitis strains. It is also clear that most of the strains tested required two or three times as much penicillin for in-vitro inhibition as did the standard strain of staphylococcus.

TREATMENT OF ACUTE CASES

All patients with acute diphtheria received antitoxin in doses depending on the severity of the case. A single batch of crystalline penicillin (sodium salt) was used to treat most of the cases. The standard adult dose was 60,000 units given intramuscularly four-hourly during the day-time only (daily dosage 240,000 units). Children aged 0–4 years received a third, and children aged 5–10 years two-thirds, of the adult dose. Children over 10 years were treated as adults.

A bacteriological check was kept on acute cases by swabbing the nose and throat every other day during

SELECTION OF NURSES FOR A MENTAL HOSPITAL

THE Cassel Hospital for Functional Nervous Disorders has a respectable tradition in the training of psychiatric nurses, and indeed offers a hospital certificate in psychological nursing. As the annual report for 1946 points out, the nursing of patients with neurosis makes considerable demands on the emotional maturity of the nurse; and in the last few years nurses joining the staff have been chosen by a selection procedure which endeavours to assess this quality.

The system was introduced by Dr. C. H. Rogerson (who was later succeeded as medical director by Dr. T. F. Main). He and his medical and nursing colleagues agreed that the personalities of suitable candidates would differ widely and that the one question to be answered was "how is she likely to perform in this hospital?" In the attempt to answer it each candidate is asked to attend for a whole day—from 9.30 A.M. till tea-time—as one of a group of eight.

Facts about her age, schooling, training, and experience are collected on the application form, as well as details relating to psychosomatic symptoms and general health. When she arrives she is received by the matron and a sister in the staff common-room, and is introduced to her fellow candidates over a cup of tea. Toward 10 o'clock the matron tells the group something of the hospital and its purpose, and the sister then takes them on a tour of the premises, introducing them to any members of the staff they meet, and answering their questions. At 10.45 A.M. they return to the common-room and meet the rest of the staff over morning coffee. At 11 A.M. they go to another room, and sitting in a friendly semi-circle round the sister begin their written tests. These aim at giving the candidates opportunities "to respond, in their own characteristic ways, to the same evocative emotional stimuli," and thus to reveal something of their own emotional patterns. Candidates are therefore asked to give an account of the scene portrayed in a picture (Murray's cards are used), and to write a series of sentences each containing a stimulus word (15 seconds being allowed for the composition of each sentence). Each nurse is invited to write a short description of herself as a person; to describe in two minutes the most exciting moment of her life; and to do an intelligence test of the kind which shows capacity to learn.

This carries the group to lunch-time, when they lunch in the cafeteria with staff and patients. At 2 o'clock interviews begin. Two psychiatrists are available, each interviewing four candidates, the interviews lasting 10–40 minutes; meanwhile the matron sees each candidate, as soon as she is free, for a quarter of an hour. The sister conducts them to and from the interviews and gossips with them between whiles.

At the end of the interviews the psychiatrist has in his hands much relevant material about each candidate: the details on the application form, the intelligence quotient, the summary of "personality pointers," and the material he has elicited in talk. The atmosphere throughout the test is made so easy and informal, and the candidate's self-respect is so carefully regarded, that she is usually ready at the interview to tell more about herself, and even in some cases to discuss "stress points" within herself. The matron decides whether she likes her or not—an important decision, since she must work with her.

At 3.30 the whole group meet again with one of the psychiatrists, who initiates a group discussion; here each candidate is seen, so to speak, in social action, and shows her capacity to form easy reciprocal relations with others. At 4.30 the candidates take tea with the matron and are given the opportunity to talk over and criticise the selection procedure; this enables them to leave the hospital on a note of professional respect and equality. The selection team—psychiatrists, matron, and sister—then discuss them, and the matron, aided by the selectors, makes her final choices. The results have shown the value of the tests, and the method has proved acceptable to nurses, whether engaged or not.

Committee on Social Workers in Mental Health

The Minister of Health has set up a committee "to consider and make recommendations upon questions arising in regard to the supply and demand, training and qualifications of social workers in the mental health service. The committee is to present an interim report on these questions in relation to psychiatric social workers." The members are:

Prof. J. M. Mackintosh (chairman); Dr. J. B. S. Lewis, Dr. R. M. Bates, Dr. R. H. Parry, Mr. Bryn Roberts, Dr. Kenneth Soddy, Miss S. Clement Brown, Miss Eileen L. Younghusband, Miss C. V. Barclay, Miss J. M. Mackenzie. Mr. A. Forbes of the Ministry of Health will act as secretary.

Charing Cross Hospital

Field-Marshal Viscount Montgomery will deliver inaugural address to the medical school on Thursday, at 4 P.M.

Welsh National School of Medicine

On Tuesday, Oct. 5, Prof. E. D. Adrian, O.M., F.R.S., deliver the opening address of the session at the 10, The Parade, Cardiff. He is to speak on the Medicine.

Society of Apothecaries

There has been an alteration in the programme course on modern therapeutics announced in our columns last week. Dr. Basil Parsons-Smith will now lecture on Oct. 25. He will speak on Hypertension.

Royal College of Obstetricians and

Dr. Emil Novak, associate in gynæcology in the Hopkins Medical School, Baltimore, will deliver the Anglo-American lecture on Friday, Oct. 1, at 2.15 P. 1, Wimpole Street, London, W.1 (and not at the co viously announced). He is to speak on Certain Fun Tumours of the Ovary.

Royal Society of Medicine

Dr. Philip S. Hench, of the Mayo Clinic, will give the Hyde lecture before the section of physical medicine society on Wednesday, Oct. 13, at 4.30 P.M. The ti lecture is A Critical Evaluation of Current R Rheumatoid Arthritis. The officers of the section those who are not fellows of the society, but who wish to apply for tickets to Dr. Doris Baker, the hon. of the section, at 1, Wimpole Street, London, W.1.

Institute for the Scientific Treatment of Del

Dr. J. D. W. Pearce is giving a course of 12 lectures Psychology of Delinquency, on Thursdays, at 6.30 P.M., ning on Sept. 30. Mr. Hermann Mannheim, DR. JUR Dr. Edward Glover will also give six lectures on and the Psychopathology of Crime, at 6.30 P.M. on T during November and January. Particulars of these other lectures to be given at the institute may be had secretary, 8 Bourdon Street, Davies Street, London, W.1.

Commonwealth Travelling Professorship

The Royal College of Physicians has nominated Dr. G. Pickering, professor of medicine in the University of at St. Mary's Hospital, as Commonwealth travelling for 1949. He will visit Australia and New Zealand in part of that year.

Mr. Arthur Sims, of New Zealand, endowed a Co travelling professorship, under the ægis of the Royal Surgeons of England, the Royal College of Physicians of the Royal Australasian College of Physicians, and the Australasian College of Surgeons, providing for the ment annually of a travelling professor to visit Australia, New Zealand, South Africa, and Canada to assist advancement of medical science either by lecturing, investigating, or engaging in research.

Sir Weldon Dalrymple-Champneys, F.R.C.P., will take as chairman of the council of the Royal Sanitary on Oct. 1.

ÇORRIGENDUM.—*Meningo-encephalitis in Man Due* *Louping-ill Virus.* On p. 454 the last line of the first c should read: ". . . total of 500,000 units. . . ." In the line of the second column, for Dec. 2 read Oct. 2.

Diary of the Week

SEPT. 26 TO OCT. 2

Tuesday, 28th

EUGENICS SOCIETY
5.30 P.M. (Burlington House, Piccadilly, W.1.) Mr Bloomfield: The Eugenics of the Utopians—the of the Eugenists.

Wednesday, 29th

INSTITUTE OF LARYNGOLOGY AND OTOLOGY, 330, Gray's Inn W.C.1
10 A.M. Mr. A. C. Deverell: Relationship of Dental Dis Diseases of the Throat, Nose, and Ear.

Friday, 1st

ROYAL COLLEGE OF OBSTETRICIANS AND GYNÆCOLOGISTS
2.15 P.M. (1, Wimpole Street, W.1.) Dr. Emil Novak more): Certain Functioning Tumours of the (Anglo-American lecture.)

UNIVERSITY OF GLASGOW
3 P.M. (Chemistry building.) Prof. Geoffrey Jefferson, Contribution of Sir William Macewen to Neuro and its Sequels. (Macewen lecture.)

PENICILLIN IN DIPHTHERIA

›RT OF A SUBCOMMITTEE OF THE PUBLIC HEALTH LABORATORY SERVICE*

his investigation the penicillin-sensitivity of 284 of *C. diphtheriæ* isolated in different parts of the was measured. An attempt was also made to it if penicillin treatment shortened the time of e of *C. diphtheriæ* in acute cases of faucial diph- and eliminated the organism in persistent throat s. Information on the clinical effect of penicillin s of diphtheria was not sought. Though there is l agreement that *C. diphtheriæ* is sensitive to lin in laboratory tests, the evidence for this view rests on separate reports on a few strains (Long This criticism also applies to much of the work penicillin treatment of acute cases and chronic s. though Karelitz et al. (1947) have treated te cases of diphtheria with encouraging results. e of the low incidence of diphtheria in this y we tried to secure sufficient material for ination by carrying out our tests in eight tory areas.†

SENSITIVITY OF STRAINS TO PENICILLIN

hnique.—A standarised and stabilised penicillin on was distributed every fortnight by Dr. Joseph r, of Glaxo Laboratories Ltd., and this was used ll tests. The requisite amount of penicillin was d in bulk to nutrient broth (pH 7·5) which contained 'Lab Lemco,' 1% proteose peptone, 0·5% sodium ide, and 5% of a single batch of heat-inactivated -filtered horse serum ; 5 ml. of this broth was used ach dilution of penicillin, which ranged from 0·6 ·03 unit per ml. of medium. For each strain of *iphtheriæ*, therefore, six tubes containing penicillin inoculated together with a broth tube without cillin. In addition a similar control series of tubes ulated with the Oxford staphylococcus accompanied strain under test, and when a batch of strains was d it was customary to put up controls inoculated stock strains of the three types of *C. diphtheriæ*.

ch tube was inoculated with an arbitrary standard ful ('Nichrome'-wire loop of internal diameter m.) of an overnight culture of the organism grown e broth medium. Tubes were then incubated at for twenty-four hours. After thorough shaking the were examined and the turbidity was recorded. the tube at the visual end-point and from the containing the next highest concentration of illin a standard loopful was then spread on half a blood-agar plate. The number of colonies developing after overnight incubation was estimated and compared with the number obtained from a control tube. This control, with which it was intended to estimate the size of the original inoculum, was prepared by adding a standard loopful of an overnight broth-culture of the strain under test to 5 ml. of the broth medium, and plating out immediately. Subcultures from tubes yielding numbers of colonies greater than half the number from the control were, for the purposes of the test, considered not to show inhibition ; the first tube from which subculture gave less than half the number of colonies from the control tube indicated the penicillin sensitivity of the strain.

Results.—Most of the strains were tested in each of two laboratories, and only very occasionally was there more than a one-tube difference in the sensitivities recorded. Such differences were observed with twelve strains, and these were retested before they were recorded. Under the conditions of our tests the Oxford staphylococcus was inhibited by 0·1 unit of penicillin per ml. of medium. This relatively high reading may be associated with the size of the inoculum used in our tests ; with 1/500 of this inoculum the reading was 0·05 unit per ml. In two small batches of strains of *C. diphtheriæ* tested in two different laboratories where the bacteriostatic levels for the strains of *C. diphtheriæ* were above the average the Oxford staphylococcus was inhibited by 0·2 unit of penicillin, but the ratio was normal. Though it is necessary to mention these few discrepant results, the findings in the different laboratories were remarkably uniform. The results (tables I and II) show that gravis strains of *C. diphtheriæ* are rather more resistant to penicillin than intermedius, and that intermedius are more resistant than mitis strains. It is also clear that most of the strains tested required two or three times as much penicillin for in-vitro inhibition as did the standard strain of staphylococcus.

TREATMENT OF ACUTE CASES

All patients with acute diphtheria received antitoxin in doses depending on the severity of the case. A single batch of crystalline penicillin (sodium salt) was used to treat most of the cases. The standard adult dose was 60,000 units given intramuscularly four-hourly during the day-time only (daily dosage 240,000 units). Children aged 0–4 years received a third, and children aged 5–10 years two-thirds, of the adult dose. Children over 10 years were treated as adults.

A bacteriological check was kept on acute cases by swabbing the nose and throat every other day during

TABLE III—RESULTS OF TREATMENT OF ACUTE CASES OF DIPHTHERIA WITH PENICILLIN

Type of *C. diphtheriæ*	No. of cases treated	Proportion of cases treated "successfully"*		No. in which treatment failed
		Three days	Six days	
Gravis ..	29	7/14	12/15	10
Intermedius ..	17	9/12	3/5	5
Mitis	19	10/11	8/8	1
Totals ..	65	26/37	23/28	16

* "Successful" = no positive swab later than four days from the end of penicillin therapy.

treatment and for a week thereafter. Subsequent swabs were taken at weekly intervals until the patient was discharged from hospital. All swabs were plated on tellurite medium and examined after twenty-four and forty-eight hours in the incubator.

The cases were divided into two groups: one received treatment for three days only, and the other for six days. Treatment with penicillin was considered successful if the patient had the first of a series of consistently negative swabs within four days of the end of the penicillin course. Results are shown in table III and compared in the figure with Wright's (1941) series in Liverpool.

Because of the very few cases available in most of the laboratory areas it was impossible to treat alternate cases with antitoxin alone. At one centre, however, 6 out of 13 cases were "successfully" treated with a three-day course of penicillin, whereas only 3 of 22 control cases treated in the same hospital with antitoxin alone had the first of a series of consistently negative swabs within a fortnight of admission.

TREATMENT OF PERSISTENT CARRIERS

For the purposes of the investigation a persistent carrier was defined as one known to have carried *C. diphtheriæ* in his throat for at least six weeks. Most of the carriers treated were not known to have had acute diphtheria, but a few were considered to be persistent carriers if after six weeks in hospital for acute diphtheria they still harboured the organism in large numbers At first penicillin treatment for throat carriers was given in the same doses as for acute cases. Later the dose of penicillin was increased to 500,000 units twice daily for three days. Throat and nose swabs were bacteriologically examined as for acute cases, and the test of successful treatment was the same. The results are shown in table IV.

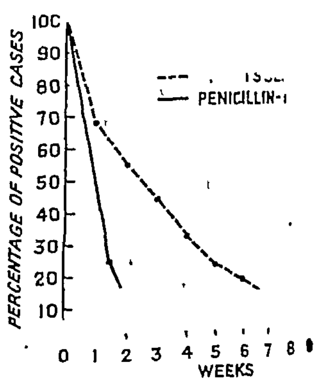
TABLE IV—RESULTS OF PARENTERAL PENICILLIN TREATMENT OF DIPHTHERIA THROAT CARRIERS

Type of *C. diphtheriæ*	No. of cases treated	"Successfully" treated	Failures
Gravis	14	3	11
Intermedius ..	3	2	1
Mitis	14	8	6
Totals ..	31	13	18

Most of the carriers treated with the same doses as acute cases were given a six-day course; but 9 carriers were given 500,000 units of penicillin twice a day for three days, with 3 successes and 6 failures, 5 of the failures being of the gravis type. Sensitivity tests were performed on 5 strains of *C. diphtheriæ* (4 gravis and 1 intermedius) isolated from carriers before and after penicillin treatment. None of the strains isolated after treatment showed an increased resistance to penicillin in the test-tube. Among the 18 carriers in whom treatment failed 7 were known to have diseased tonsils and of these 5 later had their tonsils removed, with subsequent cure of the carrier state. Besides the carriers listed in table IV, 2 nasal carriers were treated succ intramuscular penicillin for three days; 3 further anterior nasal diphtheria were treated three-hourly a local spray of penicillin solution containing a dose of 100,000 units. Treatment was given for days and all 3 cases satisfied the criterion of cur

COMMENT

Though penicillin-sensitivity tests are done in many laboratories, we found it at first difficult, even with a relatively simple culture to achieve a technique which would ensure quantitatively uniform from one laboratory to Preliminary investigation was carried out on such as the size of inoculum, the sample and prep horse serum used, clumping of certain strains of diphtheria bacillus, and the method of reading points. When these difficulties had been most of our strains of *C. diphtheriæ* were finally tested in two laboratories, and the results were very uniform.



Rate of disappearance of C. diphtheria of faucial diphtheria treated with

Most of the strains required two or three times as much penicillin for inhibition as does the Oxford staphylococcus. Only 2 strains were encountered which had a ratio greater than six. From table II analysis has shown that the differences in the mc tivity of each of the three types are all significant is little doubt that the gravis strains are more to penicillin than the mitis type. The scatt sensitivities of the three types, as measured by deviations, shows that *the mitis type differs* si from intermedius and gravis. This greater sca resistance of the mitis type of *C. diphtheriæ* is understandable in view of the greater biological in this group of strains. The results, however, clear *that strains of C. diphtheriæ* of all three tested are sensitive in vitro to concentrations of which can readily be reached in the body.

Because of the limited number of cases and our disposal we could not carry out the type of penicillin treatment which is obviously required rate of elimination of *C. diphtheriæ* from the throat of patients may depend on several variables, as the type or even the strain of *C. diphtheriæ*, the of the patient's tonsils, his age, and whether or not has been *immunised*. We have treated sporadic of diphtheria in different parts of the country, and results may therefore not be strictly comparable those of other workers. Table III shows that 75 65 acute cases treated with penicillin were free of infecting organism within ten days of starting trea and that 26 (70%) of 37 *acute cases treated for three* had become bacteriologically negative within a

In the figure we have compared *Wright's* (1941) L series of cases of acute diphtheria treated with anti alone with our penicillin-treated cases. Only 45 Wright's cases were bacteriologically negative fo days after admission to hospital, compared with of our penicillin-treated cases. Wright's figur differences in the rate of clearance of the three *C. diphtheriæ* from the nose and throat of acute gravis type tending to persist longer than mitis or medius. This suggests that the precise rate of ppearance of *C. diphtheriæ* in any series of cases be influenced by the type composition of that series. mparing our results with those obtained at Liverpool ust also be remembered that the two sets of figures obtained at very different times, and that our e is based on only a fifth of the number of cases ained by Wright. It is also possible that cross- tion may have prolonged the carrier state in some Vright's cases, though his investigation deals with type with which the patient was originally infected. ever, Wright's findings in children are essentially lar to those obtained by Hartley and Martin (1919–20) ldiers and by Thomson et al. (1926–27) in a London r hospital. Wright's curve being taken as an uate basis for comparison, the curve for the rate of ppearance of *C. diphtheriæ* in penicillin-treated cases much more steeply. Our series included a propor- of immunised patients, but there was no evidence immunisation affected the clearance-rate.

right's finding and our own small group of control s support the view that penicillin treatment tens the duration of carriage of *C. diphtheriæ* in e cases, and that our results would not have been ined in cases treated with antitoxin alone. The ll group of cases caused by the mitis type of *liphtheriæ* appeared to respond best to penicillin tment. Apart from any possible clinical benefit h penicillin treatment may confer, the early elimina- of *C. diphtheriæ* is desirable to reduce the risk of s-infection and, in many instances, to shorten the ent's stay in hospital.

enicillin treatment of persistent carriers has not, in doses used, given very encouraging results, but the ber of carriers treated was too small for definite lusions to be drawn. Of 31 carriers treated 13 eared to respond to penicillin, but possibly some of e would have become clear spontaneously during period of test. The higher doses of penicillin ocated by Long (1947) apparently gave in a few of carriers no better results than the smaller doses l earlier. Our records suggest that it may well be er to prevent with penicillin the acute case from oming a convalescent carrier than to cure the estab- ed carrier condition. If this is so, there is every son to begin penicillin therapy as early in the disease possible and not to wait until the diphtheria organism become firmly established in diseased tonsils.

SUMMARY

enicillin-sensitivity tests were carried out on 284 ains of *C. diphtheriæ* isolated in different parts of the ntry. Most of the strains tested were two or three es as resistant to penicillin as the Oxford staphylo- cus. Gravis strains of *C. diphtheriæ* were more istant to penicillin than intermedius, and intermedius re more resistant than mitis types.

Of 65 acute cases of faucial diphtheria treated with nicillin, 26 of 37 receiving a three-day course, and of 28 receiving a six-day course, became free from infecting organism within four days of the end of atment. In 31 persistent diphtheria carriers penicillin atment was followed by the rapid disappearance of organism from the throat in only 13 cases.

Ve wish to thank Dr. Joseph Ungar, of Glaxo Laboratories, supplying the penicillin for sensitivity tests; and nerous medical officers of health and clinicians who ted the cases and carriers.

THE rapidity with which the scientific and therapeutic advances on folic acid or pteroylglutamic acid (Spies 1947), thymine or 5-methyl uracil (Spies et al. 1946), and vitamin B_{12} (West 1948, Spies et al. 1948a and b) have been made is unparalleled. Within three years these three compounds have been found to produce blood regeneration in certain types of macrocytic anæmia. Each has offered the prospect of specific therapy with a pure chemical compound. The molecular structures of thymine and of folic acid are known, and much work is being done to elucidate the structure of vitamin B_{12}.

Under the scrutiny of physicians these materials must be appraised in respect to their effect on man. It is well known that the response of patients to liver extract or to folic acid is extremely variable. Some respond maximally to much smaller doses than do others. This extreme variation in the individual response under test conditions made it desirable to observe the effect of folic acid, thymine, and vitamin B_{12} in the same person in the same degree of relapse, under similar conditions, and on the same diet. The present report is limited to a study of the blood response to each of these substances in a patient with nutritional macrocytic anæmia, one with pernicious anæmia, and one with tropical sprue.

Using the diagnostic criteria and laboratory methods previously described (Spies 1947), we selected and studied three patients. Each was admitted to hospital in relapse three times and on each admission was given a different pure chemical substance, while the diet and the conditions of the study were kept constant.

CASE-RECORDS

Case 1.—A white man, aged 51, was admitted to the Jefferson-Hillman Hospital, Birmingham, Alabama, in April, 1946, complaining of extreme weakness. His family history and previous personal history were irrelevant. Three years before admission, while working as a coalminer, he developed shortness of breath, tinnitus, vertigo, "fluttering of the heart," "shimmering of the vision," and frequent bleeding of the gums. These symptoms progressed rapidly, and within two months of their onset the patient was forced to stop working and was admitted to a hospital, where he was treated with liver extract. He soon became asymptomatic and was discharged from the hospital. On returning home he resumed eating the same type of diet he had eaten as long as he could remember. It consisted of grits, bread, syrup, fat, two eggs, and two glasses of milk daily. He rarely ate meat,

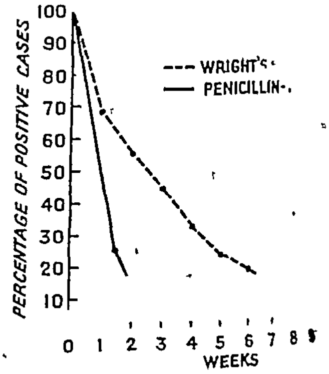
COMMENT

Though penicillin-sensitivity tests are done in many laboratories, we found it at first difficult, even with a relatively simple culture to achieve a technique which would ensure quantitatively uniform from one laboratory to Preliminary investigation was carried out on as the size of inoculum, the sample and prep horse serum used, clumping of certain strains diphtheria bacillus, and the method of reading points. When these difficulties had been most of our strains of *C. diphtheriæ* were finally tested in two laboratories, and the results were very uniform.

Most of the strains required two or three times as much penicillin for inhibition as does the Oxford staphylococcus. Only 2 strains were encountered which had a ratio greater than six. From table II analysis has shown that the differences in the tivity of each of the three types are all significant, is little doubt that the gravis strains are more to penicillin than the mitis type. The scatter sensitivities of the three types, as measured by deviations, shows that the mitis type differs from intermedius and gravis. This greater scat resistance of the mitis type of *C. diphtheriæ* is understandable in view of the greater biological in this group of strains. The results, however, clear that strains of *C. diphtheriæ* of all three tested are sensitive in vitro to concentrations of p which can readily be reached in the body.



Rate of disappearance of *C. diphtheriæ* of faucial diphtheria treated

Because of the limited number of cases and our disposal we could not carry out the type of penicillin treatment which is obviously required. rate of *elimination of C. diphtheriæ* from the throat of patients may depend on several variables as the type or even the strain of *C. diphtheriæ*, the of the patient's tonsils, his age, and whether or has been immunised. We have treated sporadic of diphtheria in different parts of the country, and results may therefore not be strictly comparable those of other workers. Table III shows that 75 65 acute cases treated with penicillin were free infecting organism within ten days of starting trea and that 26 (70%) of 37 acute cases treated for three had become bacteriologically negative within a

In the figure we have compared Wright's (1941) series of cases of acute diphtheria treated with anti alone with our penicillin-treated cases. *Only* 45% Wright's cases were bacteriologically negative fo days after admission to hospital, compared with of our penicillin-treated cases. Wright's figur differences in the rate of clearance of the three *C. diphtheriæ* from the nose and throat of acute

l. Improvement continued, and he was discharged weeks after admission. Gastro-intestinal radiography nth after therapy showed a continuous barium n.

nd *Admission.*—He remained well until April, 1947, he again began to have diarrhœa and loss of appetite. s visiting in the country at the time and did not come to spital until a month after the onset of these symptoms. s second admission the clinical and laboratory findings similar to those on his previous admission, except he red-cell count was 1,170,000 per c.mm., Hb 5·1 g. 0 ml. (33%), and reticulocytes 2·2%.

was given 10 mg. (10,000 µg.) of synthetic folic acid by daily for fourteen days. The blood response is shown . 3. Clinical improvement began about the time the locytes began to rise on the fourth day of therapy; reness of his tongue was relieved, his appetite returned, e began to get stronger. By the ninth day of therapy wel actions had decreased from 10 to 3 daily, and the were better formed and more normal in colour. By me he was discharged, three weeks after admission, he ained 10 lb. and felt well.

rd *Admission.*—He had no recurrence of symptoms until 1948, when he developed severe bronchitis and lost ppetite. Within a week of the onset he began having rately severe diarrhœa, soreness of the tongue, and stric distress. He was in bed and unable to come to the tal for four weeks after he became ill. When he came and dmitted for the third time his tongue was moderately ned: he was very pale and weak and was having 5 soft or liquid yellowish-brown stools daily. His red- count was 2,500,000 per c.mm., Hb 7·8 g. per 100 ml.), and reticulocytes 1%. The other laboratory findings as on his first admission.

was given a single injection of 23 µg. of vitamin B_{12}. blood response is shown in fig. 3. His appetite oved and he felt well four days after therapy, and eadily gained in strength. Eight days after therapy wel movements decreased to 2 soft fairly well-formed s daily.

ise 3.—A white man, aged 46, was admitted to the man-Jefferson Hospital, in March, 1946, complaining of al weakness, dyspnœa, palpitation on exertion, soreness he mouth and tongue, swelling of the legs and feet, and sthesiæ of the extremities. His family history and previous onal history were irrelevant. A year before his admission oted that he became tired very easily, had difficulty in thing, and had palpitation on exertion. These symptoms ually became more severe. Six months after their onset his tongue, which he had noted to be abnormally red, began burning, especially when he ate "sour or hot" foods. About three months later he began to have numbness of his hands and feet and swelling of his feet and ankles.

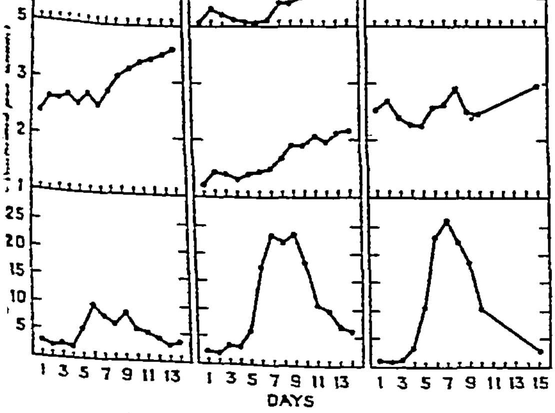


Fig. 3—Blood responses of case 2.

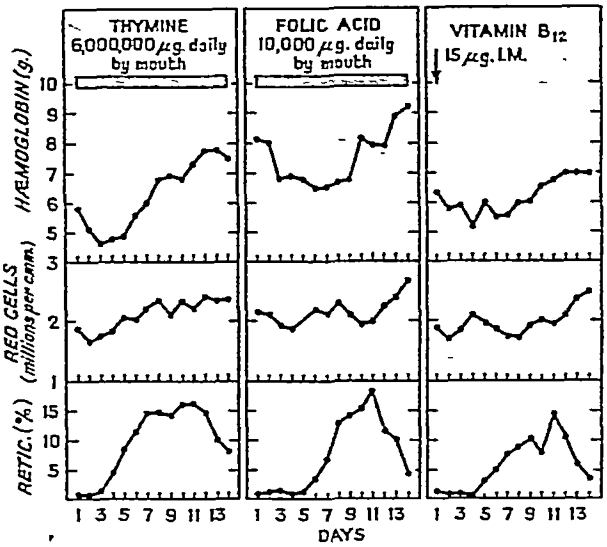

Fig. 4—Blood responses of case 3.

First Admission.—He was pale and looked weak but not acutely ill. The skin, nail beds, and conjunctivæ were very pale. His tongue was smooth and red; the buccal mucosa was red, and the gums were swollen and injected. Neurological examination showed sensory changes suggesting peripheral neuritis.

Gastric analysis showed no free hydrochloric acid after histamine stimulation. Gastro-intestinal radiography was normal. An oral glucose-tolerance test showed a flat curve. The urine was normal. The stools contained no ova, parasites, or occult blood. The red-cell count was 1,860,000 per c.mm., Hb 5·8 g. per 100 ml. (38%), and reticulocytes 0·3%. The sternal bone-marrow showed typical megaloblastic arrest. Pernicious anæmia was diagnosed.

The patient was kept on a diet devoid of meat and meat products. After the base-line determinations had been completed, he was given 6 g. (6,000,000 µg.) of synthetic thymine by mouth daily for fourteen days. The blood response is shown in fig. 4. Though the sternal bone-marrow just after the peak of reticulocytosis revealed a normoblastic reactive stage, his anæmia began to relapse soon after therapy was discontinued. Clinically his improvement was slight; the stomatitis, the glossitis, and the nervous symptoms did not improve.

Second Admission.—In December, 1946, the weakness and dyspnœa recurred, but he did not come to the clinic until May, 1947, when he had become too weak to continue working. On his second admission the physical findings were essentially the same as on his previous admission. His red-cell count was 2,150,000 per c.mm., Hb 8·1 g. per 100 ml. (53%), and reticulocytes 0·6%. The other laboratory findings were as on his first admission.

He was given 10 mg. (10,000 µg.) of synthetic folic acid daily by mouth for ten days. Fig. 4 shows his blood response. As his blood-levels rose he gained strength, and the glossitis and stomatitis improved, though they did not disappear entirely.

Third Admission.—In March, 1948, the patient developed very severe glossitis, stomatitis, and weakness, and was admitted for the third time. His red-cell count was 1,090,000 per c.mm., Hb 6·3 g. per 100 ml. (41%), and reticulocytes 1%.

He was given a single injection of 15 µg. of vitamin B_{12} intramuscularly. His blood response is shown in fig. 4. Definite fading of the hyperæmia of the tongue and the mucosa of his mouth was observed forty-eight hours later. Five days after the injection of vitamin B_{12} the colour of the mucosa was almost normal. Regeneration of the lingual papillæ was apparent by the thirteenth day. A remarkable improvement in his strength and vigour paralleled his blood response.

poultry, cheese, green vegetables, or fruit. Fig. 1 shows that his diet was deficient in many nutrients, particularly nicotinic acid and ascorbic acid. Except for moderate weakness he remained well until April, 1946, when he developed moderately severe diarrhœa and his weakness became severe. At that time he came to the nutrition clinic seeking treatment and was admitted to the hospital.

First Admission.—He was pale and seemed weak but not acutely ill. His skin was very pale and slightly icteric. The skin on the dorsum of the hands was moderately thickened, pigmented, furrowed, and inelastic. On the elbows, across the scapulæ and spine, and round the ankles the skin was thickened and wrinkled. The palpebral conjunctivæ were moderately pale. There was bilateral generalised injection of the ocular conjunctivæ. In each eye, on the nasal side, there was a severely injected pterygium, which extended on to the cornea. The buccal mucosa was pale and œdematous. The nail beds were extremely pale. Neurological examination showed nothing abnormal.

Gastric analysis showed free hydrochloric acid in the gastric contents. Gastro-intestinal radiography was negative. An oral glucose-tolerance test showed a normal curve. The urine was normal. The stools contained no ova, parasites, occult blood, or urobilin. The icteric index was 10·9 units. The red-cell count was 2,220,000 per c.mm., Hb 10·7 g. per 100 ml. (70%), and reticulocytes 2·4%. The sternal bone-marrow showed typical megaloblastic arrest. Nutritional macrocytic anæmia was diagnosed.

The patient was kept on a diet devoid of meat and meat products. After the base-line studies had been completed, he was given 6 g. (6,000,000 µg.) of synthetic thymine daily by mouth for fourteen days. The blood response is shown in fig. 2. The patient's strength gradually returned as his blood-levels rose and his diarrhœa subsided. When he was discharged from hospital three weeks after admission he volunteered that he felt better than he had for many months.

Second Admission.—He remained well until January, 1947, when he began having occasional diarrhœa, with watery stools, soreness of the tongue, bleeding of the gums, and a recurrence of weakness. On his second admission to the hospital his red-cell count was 2,170,000 per c.mm., Hb 8·8 g. per 100 ml. (58%), and reticulocytes 1·4%. The results of gastric analysis, glucose-tolerance test, stool studies, analysis of urine, and sternal bone-marrow study were essentially the same as on his previous admission.

He was given 10 mg. (10,000 µg.) of synthetic folic acid daily by mouth for ten days. The blood response is shown in fig. 2. His diarrhœa stopped six days after the start of therapy. He gained strength rapidly and was discharged two weeks after admission.

Third Admission.—In April, 1948, the patient rather suddenly developed anorexia, general weakness, and slight soreness of the mouth and tongue. These symptoms progressed rapidly for a week, and he came to the nutrition clinic. On his third admission his red-cell count was 2,020,000 per c Hb 6·5 g. per 100 ml. (42%), reticulocytes 3·6 results of gastric analysis, glucose-tolerance test, stool and urine analysis were essentially unchanged. examination revealed nothing remarkable except severe glossitis than had been observed during any pre relapse of his anæmia.

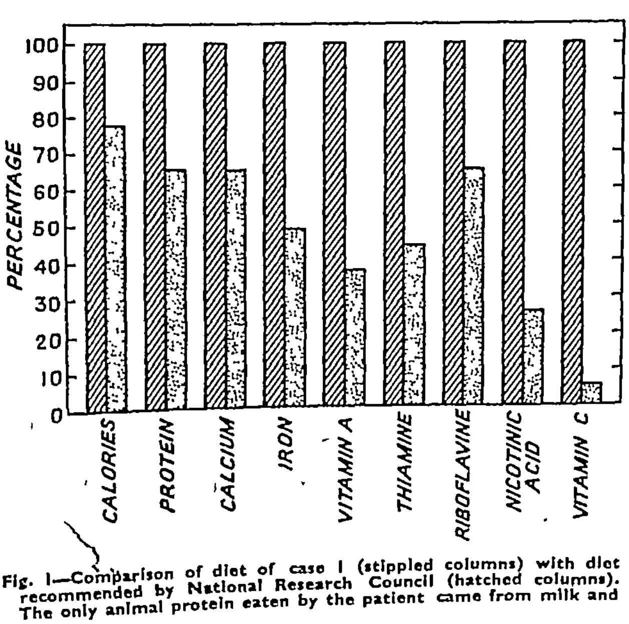

Fig. 1—Comparison of diet of case 1 (stippled columns) with diet recommended by National Research Council (hatched columns). The only animal protein eaten by the patient came from milk and eggs.

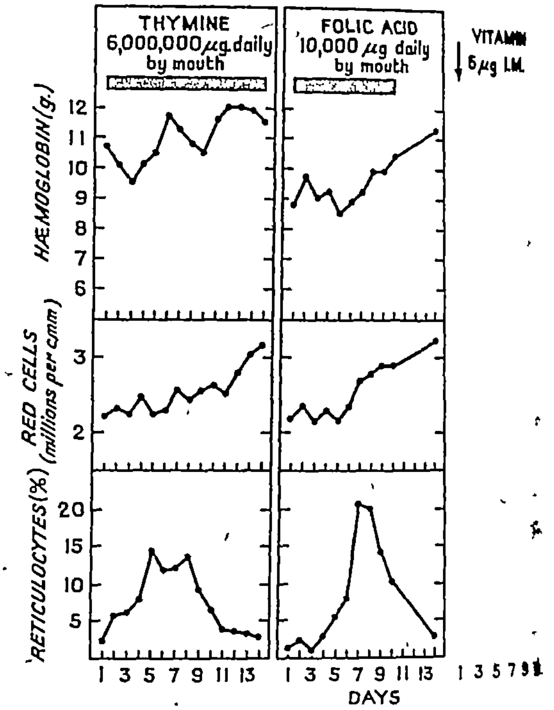

Fig. 2—Blood responses of case I.

The patient was given a single injection of 6 µg of B_{12} intramuscularly. The blood response is shown in The glossitis had disappeared by the fifth day injection, and he quickly and steadily gained strength.

Case 2.—A white Cuban farmer, aged 70, was to the General Calixto Garcia Hospital, Havana, 1946, complaining of loss of appetite, diarrhœa, and His family history and previous personal history irrelevant. Four months before admission he began have diarrhœa, consisting of 6–8 large watery yellow stools daily. Within a week his bowel movements to 11 or 12 daily; his tongue became very sore, began to have severe epigastric distress. He was eat anything but rice, soup, and milk. Ten days after illness began, weakness forced him to stop work; and then until he was admitted to hospital he spent most of time in bed. During the four months he lost 40 lb. in

First Admission.—He was pale and looked very weak ill. His skin was generally pale. His tongue was red slick. The buccal mucosa, conjunctivæ, and nail beds very pale. There were no other abnormal physical fin and neurological examination was negative.

Gastric analysis showed free hydrochloric acid in the contents. The stools were voluminous, liquid, foul- and whitish-yellow; they contained no ova, parasites, blood, or urobilin. On gastro-intestinal radiography barium column was not continuous but broken into isolated areas. An oral glucose-tolerance test show flat curve. The sternal bone-marrow showed typical m blastic arrest. The red-cell count was 2,390,000 per c Hb 9·3 g. per 100 ml. (60%), and reticulocytes 2·8%. Tr sprue was diagnosed.

The patient was kept on a diet devoid of meat and products throughout. After the base-line studies had completed he was given 10 g. (10,000,000 µg.) of synt thymine by mouth daily for fourteen days. The blood resp is shown in fig. 3. Clinical improvement began three after therapy was started; his appetite improved, and said he felt stronger. By the end of the first week he spending most of the day out of bed. The diarrhœa bega subside about this time; the stools became fewer and le s known that, if the infant is provided with a ntly high concentration of Rh-negative cells, sitive cells fall to a low level or disappear completely while, evidently because the stimulus to the pron of new cells has been removed (Mollison 1943). transfusion of Rh-negative cells will thus also a replacement of Rh-positive cells by Rh-negative ut will leave the infant to excrete a far larger r of Rh-positive cells.

CORRECTION OF ANÆMIA

discussing the treatment of hæmolytic disease of ewborn the impression must not be given that ation of tissue damage is the only object of treat-

Some deaths take place within 24 hours of birth, e believe that the mechanism in this group of deaths is different. Those infants who die soon birth are all profoundly anæmic and are usually sed. In a few cases in which we have measured nous pressure we have found it strikingly increased. ms likely that the syndrome displayed by this of cases is similar to the "hyperkinetic phase" bed by Howarth and Sharpey-Schafer (1947) in with chronic severe anæmia. In this group the of treatment must be to raise the hæmoglobin ut overloading the circulation, and this can be rationally accomplished by exchange transfusion. rtheless the prognosis in these cases is very bad, o form of treatment is likely to save many of ; there seems little doubt that they can be regarded rder-line cases of hydrops fœtalis.

ants who survive the first five days of life without ing any signs other than jaundice and perhaps pallor may later develop profound anæmia and one or more transfusions. If exchange transfusion be as simply carried out, and be shown to be as as an ordinary transfusion, it might prove to be nost satisfactory method of treatment for all cases molytic disease other than the mildest.

th the introduction by Diamond (1947) of the ique of carrying out exchange transfusions through stic catheter passed up the umbilical vein after , we felt that the needed simplification in technique been achieved, and since March, 1947, we have given method a fairly extensive trial.

METHODS

ion of Cases

e cases were selected from 63 infants seen by us $^1/_2$ years. All these 63 infants were Rh-positive were born to women whose sera contained Rh-anti-. The 33 infants not treated by exchange transfusion the umbilical vein included 6 born dead or moribund, reated by simple transfusion of Rh-negative blood a peripheral vein, and 14 so mildly affected as to ire no treatment.

Whenever possible, cord blood was examined. Other- a venous sample was taken as soon after birth as ible. The main examinations made were a direct mbs test, hæmoglobin, plasma-bilirubin, degree of hroblastæmia, and amount of free antibody. As the stigation proceeded, it became clear that it was ible to make reliable estimates of severity as a lt of these examinations, and we left untreated any nt whom we considered was mildly affected and kely to need a transfusion subsequently.

he 30 infants selected for exchange transfusion were nfants whose cord blood had either a hæmoglobin w the normal range, or a bilirubin value above the nal range, or both. Further details are given below.

nique

e have described elsewhere the technique of exchange sfusion via the umbilical vein (Mollison, Mourant, Race 1948). This technique is based on that described by Diamond (1947), though it is not known whether it differs from his in minor details.

The essentials of the technique are as follows:

Under aseptic conditions the umbilical cord is completely divided about $^1/_2$ in. from the abdominal wall. A fine transparent plastic catheter is passed up the umbilical vein until blood can be freely withdrawn (usually 2–3 in.), whereupon 20 ml. of blood is withdrawn and immediately replaced by 20 ml. of Rh-negative blood. An arrangement of stopcocks makes it possible to do this without changing the syringe. Thus 20 ml. amounts of blood are exchanged until about 350–450 ml. has been withdrawn and replaced by Rh-negative blood. In some cases an additional 50 ml. of blood is finally injected without any further withdrawal.

The whole procedure takes 1 or 2 hours. No heparin is injected into the infant, but the apparatus is rinsed with dilute heparin-saline solution from time to time.

The exchange transfusions were most often carried out within 13 hours of birth (23 cases). In the remaining 7 cases they were done 17–38 hours after birth. Occasionally in these later cases small clots were found in the umbilical vein, but these did not obstruct the passage of the catheter. In most cases there was no special difficulty in passing the catheter, once practice had been acquired.

We have used umbilical catheterisation for obtaining blood samples or carrying out tests on other infants, so that in all we have used this method in 77 cases. Though in the first few weeks, when we were acquiring experience with this method, we twice failed to pass the catheter we have since only once been unsuccessful. In this series of 77 cases we have not seen any umbilical sepsis, though only about 7 of the infants having exchange transfusions and none of the infants having simple tests were given prophylactic chemotherapy. Nevertheless, until experience has been acquired, we recommend that the infants be given prophylactic doses of penicillin for 48 hours.

In this series we have not seen any ill effects attributable to the procedure. One infant bled from the cord some hours later, but the hæmorrhage seemed to be coming from a small vessel and not from either of the umbilical arteries or the umbilical vein, and it seemed that the hæmorrhage might well have occurred in any event, simply from the unusual vascularity of the cord. Air-embolism has been reported as a danger of this method, but in the case concerned a rubber catheter was used (J. J. Van Loghem, personal communication). With the transparent polyethylene catheter that we have used throughout, minute air-bubbles can easily be seen and their introduction into the infant's circulation readily avoided.

Choice of Donor

At first ordinary stored blood was used, but it soon became clear that it had the disadvantage of being too greatly diluted with citrate. Subsequently, therefore, slightly concentrated suspensions of red cells were prepared by removing some of the supernatant plasma-citrate immediately before use. Whenever possible, donors were bled specially into relatively small volumes of anticoagulant. It was found convenient to use the mixture recommended by Ross et al. (1947)—i.e., disodium citrate 2·5 g., glucose 3 g. made up in 50 ml. of distilled water—and 500 ml. of blood was taken into a bottle containing this mixture. Alternatively the donor was bled into a bottle containing 1–2 ml. (2000 Toronto units) of heparin.

When supernatant plasma-citrate was removed, we were often left with only 400 ml. of donor's blood or even less. However, we found that, provided we had raised the red-cell count of the modified donor's blood to between 5 and 6 million red cells per c.mm., the injection of 300–400 ml. usually achieved at least an 85% exchange of red cells. Provided that the infant showed no sign of circulatory overloading, which we sometimes checked by direct measurement of venous

SUMMARY AND CONCLUSIONS

A comparative study of thymine, folic acid, and vitamin B_{12} has been made under controlled conditions on selected patients with macrocytic anæmia in relapse. One patient with pernicious anæmia, one with nutritional macrocytic anæmia, and one with tropical sprue were each admitted three times to the hospital and given a diet free from meat and meat products. Base-line determinations were made on each admission. Each compound produced a blood response and a definite clinical improvement.

The fact that three distinct chemical compounds have proved effective in each of three distinct syndromes suggests that we may learn a great deal about the pathogenesis of these diseases.

From these and other studies by us it appears that several thousand times the weight of thymine is required to produce a response similar to that produced by folic acid, and that several thousand times the weight of folic acid is required to produce a response similar to that produced by vitamin B_{12}. These findings suggest that vitamin B_{12} is by far the most potent antianæmic substance known.

This work was aided by grants from the Martha Leland Sherwin Memorial Fund, the *Birmingham Citizens Committee*, and the Fundacion de Investigaciones *Medicas* of Havana, Cuba.

The thymine was supplied by Dr. J. A. Aeschlimann, of Hoffmann-LaRoche Inc.; the folic acid by Dr. Benjamin Carey and Dr. Stanton Hardy, of Lederle Laboratories Inc.; and the vitamin B_{12} by Dr. Augustus Gibson, of Merck and Company, Inc.

EXCHANGE TRANSFUSION IN HÆMOLYTIC DISEASE OF THE NEWBORN

P. L. Mollison
M.D. Camb., M.R.C.P.

M. Cutbush
B.Sc. Melb

From the Medical Research Council Blood Transfusion Research Unit, Department of Obstetrics, Postgraduate Medical School of London

In 1946 Wallerstein pointed out that the treatment of hæmolytic disease by repeated transfusion of Rh-negative blood did not prevent some infants from dying of "toxæmia," and he suggested that withdrawal of part of the infant's blood, with simultaneous replacement by Rh-negative blood, might be more successful by removing end-products of red-cell breakdown. He found that, if 250 ml. of the infant's blood was withdrawn from the sagittal sinus, and 250 ml. of Rh-negative blood simultaneously transfused into a peripheral vein, about a 65% replacement of blood was achieved.

Wiener and Wexler (1946) introduced the modification of bleeding the infant from the radial artery; they considered mathematically the effect on the composition of the infant's blood of simultaneous bleeding and withdrawal, and plotted a curve showing the percentage exchange after the withdrawal and injection of increasing amounts of blood. They concluded that, if the exchange were continued until an amount equivalent to twice the infant's initial blood volume—i.e., 2 × 250 ml.—had been withdrawn and replaced by Rh-negative blood, 86% of the cells remaining in the infant's circulation should be Rh-negative. Wiener et al. (1948) have since suggested that even more massive replacements should be performed, and state that an exchange of 1000 ml. leads to a replacement of about 98% of the infant's red cells.

MECHANISM OF TISSUE DAMAGE

Discussion of the treatment of hæmolytic the newborn is greatly handicapped by the any real understanding of the mechanism of the to the brain and liver which occurs in some causes all the unpleasant sequelæ and many deaths. Clearly, if this damage were fully at birth, little could be hoped for from su treatment. Vaughan (1946) and Parsons (1947) drawn attention to the fact that infants who damage to the liver and brain tend not to sho pronounced anæmia, and this has led them to that the damage may be due to a direct antibody on the tissues rather than to any indirect of blood destruction. However, the matter controversial, and the following points may above-mentioned observations in a slightly differen

First, though anæmia can be readily d examining cord blood, in which the range of values is fairly narrow, it is far harder to interpret globin estimations made in the few days after It is now accepted that at birth the infant variable amount of blood from the placenta to the time at which the cord is tied, and leads to a variable increase in hæmoglobin values birth (DeMarsh et al. 1942). This widens the range of values and may mask a moderate We have observed that an infant whose cord contains a concentration of hæmoglobin well normal range may receive a sufficient amount of from the placenta to acquire a value, a few hou birth, which lies within normal limits. Thus a hæmoglobin value during the first day or two can certainly not by itself be taken as exclu operation of a hæmolytic process.

Secondly, even the maintenance of a high hæ value for many days after birth does not possibility that a very rapid destruction of being fully compensated by a rapid regenera have observed a case in which an infant wi deep jaundice maintained a hæmoglobin 120% between the 4th and 7th days of life found by cell-survival experiments to be d 50% of transfused Rh-positive cells in two days.

Thirdly, in our experience, infants who are pr anæmic at birth are likely to die within 24 hours; less many are stillborn. Thus there is a tende infants who are severely anæmic at birth not long enough to develop kernicterus.

These three points make it possible that tissue may, after all, prove to be specially associated rapid blood destruction. That anti-Rh has a action on the tissues of a Rh-positive infant doubtful, since we have sometimes observed a amount of free Rh-antibody persisting in the of an affected infant for many weeks after treat a simple transfusion, without the development of signs of damage to the liver or the brain.

It remains doubtful whether the tissue sometimes associated with hæmolytic disease is esta at birth, and we believe there is some evidence it may, at least sometimes, mainly occur after It is possible that the poor excretory capacity of liver in the first few days of life is concerned, and of some interest that deaths from the "toxic st of hæmolytic disease take place at 2–4 days, just physiological hyperbilirubinæmia in the normal infant is at its highest. At all events there is su doubt about the cause of deaths at 2–4 days to it worth while to try the effect of removing as as possible of the Rh-positive cells very soon after and replacing them by Rh-negative cells by exch transfusion.

f Exchange

he accompanying figure are plotted estimates of umbers of Rh-positive and of Rh-negative cells in culation of an initially anæmic infant in samples at intervals during an exchange transfusion. The s blood had been artificially concentrated so that unt was 5,900,000 red cells per c.mm. The con- tion of the infant's own (Rh-positive) erythrocytes om 1,650,000 per c.mm. to 560,000 per c.mm., as the count of Rh-negative cells rose rapidly to a concentration of 4,500,000 per c.mm. At the f the exchange transfusion a further 40 ml. of gative blood was injected into the infant without rawing any more blood, and this raised the con- ation of Rh-negative cells to 4,900,000 per c.mm. far we have emphasised the exchange of red cells ave not mentioned the exchange of plasma con- nts, because we have been led to conclude that emoval of plasma constituents from the infant's ation is unlikely to play any considerable part in tcome. We have found that the amount of free tibody removed by exchange transfusion is less would be expected if the infant's total amount ibody were present in the plasma at the beginning transfusion. It seems that, as with other plasma- ns, there is an equilibrium between the tissues and lasma, and that removal of antibody from the a leads to the entry into the plasma from the s of a further amount so that a new equilibrium ched at a slightly lower level. The lowering of a-bilirubin by exchange transfusion is even less, ere there is evidently the possibility of further ction of bilirubin during the transfusion.

DISCUSSION

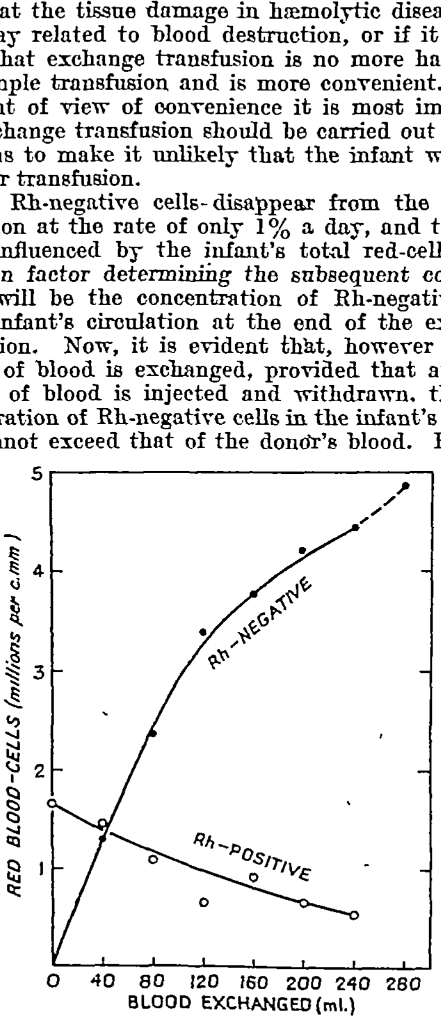
must make it clear that we do not intend, on the of only 30 cases treated by this method, to try to nstrate any effects on the morbidity and mortality molytic disease of the newborn. Cases of hæmo- disease vary from being so severe as to kill the in utero at about the 24th week to being so mild t to require any treatment. Moreover the severity nds on factors which cannot be assumed to operate e same extent in different series. For example, is the effect of a transfusion of Rh-positive blood to a Rh-negative woman on the severity of lytic disease in her subsequent offspring, which is shown by our present series. Among our cases we d 48 affected infants born to mothers who had iously only given birth to healthy children; 16 of mothers had, however, previously been transfused blood of unknown Rh type, and 8 of their ts died. Among the remaining 32 infants born nothers who had never been transfused there were 2 deaths. The difference between these figures is ly significant. This finding is in agreement with earlier observations of Diamond (1945) and Levine Waller (1946).

ow, it is clear that, if one is seeing cases of hæmolytic se in a district where, during the preceding few s, Rh typing has not been carried out before giving sfusions to women, one is likely to see more severe than if one practises in an area where few trans- ns are given or where Rh tests have been made many years. It is easy to think of other ways in h selection can lead to different kinds of cases seen by different observers. For instance, in an tric unit one certainly sees more mild cases and ably more very severe cases than in a pædiatric ; doubtless there are differences between places e families are large and those where families are l, for birth rank has some effect on severity. Also reputation of a unit for treatment might foster the fer of ca [illegible] an average severity to it.

There is little doubt that, if two observers were eacl to collect cases in different parts of the country anc to apply no treatment of any kind, a significant differenc in mortality between the two series might be found Moreover, it cannot even be assumed that the sam observer sees a similar selection of cases in two successiv years.

Apart from the above-mentioned factors one mus consider the effect of better methods of diagnosis, witl a resulting tendency to diagnose more mild cases. Thu at first sight it seems likely that the only way in whicl the value of exchange transfusion could be provec decisively would be by applying it to alternate case in competition with, for example, simple transfusion It might be possible to collect homogeneous group —e.g., infants born to mothers previously transfusec with Rh-positive blood, or, better still, infants with comparable changes in cord blood—and to treat alternat cases differently. Certainly it seems impossible t draw any conclusions from two different series unles one can be sure that the selection of the cases has beer closely similar. It may not be necessary to attemp statistical proof if further evidence can be collected t show that the tissue damage in hæmolytic disease is i some way related to blood destruction, or if it can b shown that exchange transfusion is no more hazardou than simple transfusion and is more convenient. Fron the point of view of convenience it is most importan that exchange transfusion should be carried out in sucl a way as to make it unlikely that the infant will neec a further transfusion.

Since Rh-negative cells disappear from the infant's circulation at the rate of only 1% a day, and this rate is not influenced by the infant's total red-cell count, *the main factor determining the subsequent course of* events will be the concentration of Rh-negative cells in the infant's circulation at the end of the exchange transfusion. Now, it is evident that, however large a volume of blood is exchanged, provided that an equal amount of blood is injected and withdrawn, the final concentration of Rh-negative cells in the infant's circulation cannot exceed that of the donor's blood. Further,



Estimates of concentrations of Rh-negative and Rh-positive cells in samples taken from an infant during the course of an exchange transfusion: initial red-cell count of infant 1,650,000 per c.mm.; final count of Rh-positive cells 560,000 per c.mm.; red-cell count of donor's (Rh-negative) blood 5,900,000 per c.mm.; count of Rh-negative cells in infant's circulation after exchange of 240 ml. 4,480,000 per c.mm. Thus, after the exchange of an amount of blood about equal to the infant's blood volume, an 88% exchange was effected in this case. Finally (broken line), 40 ml. of Rh-negative blood was injected without further withdrawal to secure a final count of 4,910,000 Rh-negative cells per c.mm.

pressure through the umbilical catheter, we made a practice of injecting about 50 ml. more than we withdrew.

Subsequent Investigations.—In most cases the percentage exchange at the end of transfusion was estimated by differential agglutination. In 2 cases the rate of exchange also was determined from estimates made on serial samples during transfusion.

RESULTS

Blood Examinations

The direct Coombs test was invariably positive. Very weak positives were noted in 6 cases out of 58, and these infants were all very mildly affected. However, a strong positive test was not necessarily a sign of severity.

Hæmoglobin values in cord blood were below the normal range in more than half the infants (in our laboratory the hæmoglobin level of cord blood in normal infants usually lies between 98% and 124%, 100% being equivalent to 14·8 g. of hæmoglobin per 100 ml.). The mortality was higher in infants whose cord blood was anæmic. Samples taken a few hours after birth usually showed higher values, as expected. The difficulty of diagnosing anæmia in an infant a day old is just that of trying to decide whether an adult with a hæmoglobin level of about 100% is anæmic, having been told that he may or may not have had a transfusion of three pints of blood on the previous day. (For data on the transfer of blood from the placenta to the infant see DeMarsh et al. 1942.)

The concentration of bilirubin was less than 3 mg. per 100 ml. in the cord blood of all mildly affected infants (the normal range in our laboratory is 0·5–2·5 mg. per 100 ml.). Severely affected infants had values of over 4 mg. per 100 ml., the highest being 8·1 mg. per 100 ml.

The higher bilirubin values were found in the more anæmic infants. Bilirubin values sometimes rose very rapidly after birth, and comparisons were more difficult in later samples than in cord blood.

Erythroblastæmia was invariable in anæmic infants but inconstant in mildly affected cases.

Free Rh antibody was almost invariably present in the infant's plasma, but the amount was not well correlated with the other findings.

Clinical Results

The accompanying table shows that, of the 30 infants treated by exchange transfusion, 7 died and 23 recovered. The infants that died were 1 with frank hydrops fœtalis; 3 with severe anæmia whose condition at birth was critical and who died within 24 hours of birth; and 3 less severely affected who developed profound jaundice despite exchange transfusion and died 2–4 days after birth. Only one of the 23 survivors shows signs of damage to the central nervous system.

Among the survivors are a few infants whose condition was very critical at birth. The following are examples:

Case 1.—*The mother had previously had 2 normal infants and an induced abortion. After the abortion she was transfused with three bottles of blood of unknown Rh type. This was followed by a severe hæmolytic reaction, and there is little doubt that she not only received Rh-positive blood but also was already at that time sensitised to Rh. The present infant was born 8 days before the expected date of delivery and was immediately seen to be pale and jaundiced; the spleen and liver were slightly enlarged. Blood examination 2 hours after birth showed red cells 1,150,000 per c.mm., Hb 35%, and bilirubin 11·6 mg. per 100 ml. A blood film showed that almost all the nucleated cells were erythroblasts or normoblasts, and there were 25% reticulocytes; the direct Coombs test was strongly positive. Exchange transfusion was carried out with Rh-negative blood, and at the end of the transfusion 90% of the cells in the infant's circulation were Rh-negative. However, the total hæmoglobin was only 57%, since ordinary diluted blood has been used, and a supplementary transfusion had to be given next day.* The infant's su progress was entirely satisfactory.

OUTCOME IN 63 CASES IN WHICH AN RH+ INFANT WA TO A MOTHER WHOSE SERUM CONTAINED RH ANTIBO

Type of case	No. of cases	Treatment	No. of deaths		No. of
			Within 24 hr.	At 48–96 hr.	Complete
Stillbirth and hydrops fœtalis *	7	Exchange transfusion *in 1 case*	7	..	..
Infants with initial anæmia †	18	Exchange transfusion	3	3	12
Infants without initial anæmia	11	Exchange transfusion	..	..	10
	9	Simple transfusion	..	2	7
Infants first seen after first 24 hr. of life	4	Simple transfusion	..	..	3
Infants very mildly affected	14	*No* transfusion	..	..	14
Total	63	..	10	5	46

* 5 infants born dead; 1 with hydrops lived ½ hr.: another 5 hr. and was treated by exchange transfusion.

† *Infants have only been included in this group if their hæm* was less than 65% in cord blood or less than 80% in a sample taken within 24 hr. of birth.

Case 2.—The mother's first infant was normal, but was then transfused with many bottles of blood of un Rh type. Her second infant died 4 or 5 days after b and it is recorded that it was very pale. In view of previous history the mother's third pregnancy was te at 37 weeks. The infant was pale and a little jau and examination of its cord blood showed direct test positive, Hb 59%, and bilirubin 5·5 mg. per 1 A blood film showed 20 nucleated red cells per 100 cells. At 3¼ hours after birth the plasma-bilirubi had risen to 9·3 mg. per 100 ml. An exchange tr was given, 470 ml. of blood being removed and 530 Rh-negative blood injected. By the 5th day of life infant's bilirubin concentration had fallen to 2·8 mg. *100 ml., and the infant was no longer jaundiced.* infant's hæmoglobin fell only very slowly after transfusi at 19 days of life it was still 86%; at this point no Rh cells could be detected in the circulation. By the 47th of life the hæmoglobin had fallen to 48%, but there were some Rh-positive cells present. The infant's hæm thereafter rose spontaneously, and by the age of 78 days it reached 70%. A few details are given in the following ta

Age	*Hb* (%)	*Bilirubin* (*mg. per 100 ml.*)	*Red cells* (*millions per c.mm.*)	*Rh negative cells* (*millions per c.mm.*)
3 hours ..	76 ..	9·3 ..	3·0 ..	None
5 ,, ..	121 ..	7·0 ..	5·0 ..	5·9
5 days ..	108 ..	2·8 ..	— ..	—
10 ,, ..	80 ..	0·7 ..	4·5 ..	4·5
47 ,, ..	48 ..	— ..	— ..	—
60 ,, ..	58 ..	— ..	2·0 ..	1·6
78 ,, ..	70 ..	— ..	— ..	—

At 60 days there were only 1,600,000 Rh-negat cells per c.mm. in the infant's circulation, and it m at first appear that the elimination of these cells significantly exceeded 1% a day. However, as Pick (1947) has pointed out, allowance must be made for infant's increasing body-weight. In the present c the infant had grown from 7 lb. at birth to 10½ lb the 60th day. Thus, to find the true survival-rate o must multiply 1·6 by 10·5÷7 and express this figure a percentage of 5·9. The corrected survival is then 41 which is very close to the expected figure.

INFLUENCE OF RESTRAINT ON AUTOMATIC MOVEMENTS

VALUE IN DIAGNOSIS

RE is a functional unity in the movements of all mbs in quadrupeds and man. The fore limb (arm n) of one side and the hind limb (leg in man) of her side normally move simultaneously in the same on during bodily progression.* This has been strated also in reflexes obtained in decerebrate ls (Sherrington 1898). Arm-swinging is therefore tomatic accompaniment of walking; and Wilson observed in a case of largely right-sided parkin- n that "the left arm was always advanced to a tly greater extent than usual, and this corre- ed strictly to a slower advancement of the weak leg."

omatic arm-swinging in walking is often diminished lished in extrapyramidal lesions—e.g., parkinson- f which it is one of the earliest signs—but this also ns in severe spastic hemiparesis and in slight idal lesions. According to Monrad-Krohn (1938) novement is often absent in pyramidal and yramidal lesions.

have observed that healthy people walking while ng something heavy in one hand swing the free nore than when both arms are free; and that healthy person restraint of one arm increases the tude of swing of the other. In making this test it ntial to ensure that the restrained arm makes no ment whatever.

se observations led us to test arm-swinging in is pathological conditions, and we have found that, a patient with predominantly unilateral parkinson- alks carrying a book in his sound hand, or with hand in his pocket or resting on his back, the atic swinging of the unsound arm returns or is sed. When the sound arm is released, the swinging e unsound arm is decreased or disappears. We have the same thing in encephalitic pseudoneurasthenia, nham's chorea, and hemichorea. (In some cases of ed encephalitis, and even, in some cases of overt phalitis if the patient can walk, some days may e before this phenomenon can be observed.) But rkinsonism in which the unsound arm shows much rtonus, in cerebral hemiparesis with spasticity, in lteral pyramidal lesions without hypertonus, and in id central paralysis of the arm, restraint of the sound arm does not bring back these movements in the unsound arm.

Reflexes may be linked so that inhibition of one calls forth the other reflex. For instance, swallowing and breathing are associated reflexes in that one of them must be inhibited to allow the other to act. Now, the inhibition of breathing—e.g., in a high wind—calls forth reflex swallowing. One would therefore expect that, in walking, restraint of one of the two limbs functionally associated as already described would stimulate reflexly the action of the other pair of limbs. This has been shown to be true of the arms and is probably true of the legs also, but this is difficult to prove.

Lescenko's Phenomenon

Other associated reflexes provide similar examples. Reflex blinking of one eye in normal people is strongly linked, and takes place simultaneously, with blinking of the other eye. But Lescenko has shown that if, in some cases of parkinsonism, while the patient fixes his gaze on an object, the demonstrator lowers one of the patient's upper eyelids and lifts that eyelid again, the uncontrolled upper eyelid of the other eye is automatically lowered; and, when the controlled eyelid is lowered again by the demonstrator, the uncontrolled eyelid is automatically raised.

It seems that, the normal lowering and raising of eyelids (blinking) being extremely rapid, the slower movement of the patient's eyelids by the demonstrator constitutes a form of restraint. Now, we have shown that restraint on one side causes active movement on the other. Further, the raising of the patient's eyelid by the demonstrator restrains its lowering; therefore such restraint provokes lowering of the opposite (uncontrolled) eyelid. In harmony with this finding is the fact that, in normal people, if the demonstrator prevents the subject from closing his eyes, attempts to blink are produced which are more frequent than normal.

Abduction of Legs

Raimiste (1909) has described how, in cerebral hemiplegia, restraint of active abduction of the sound leg elicits abduction of the unsound leg. According to Walshe (1921) "diverse forms of voluntary movements against resistance may, in certain cases of hemiplegia, always elicit the same response, whereas in other cases the form of the associated reactions could be completely modified according to the form of the voluntary movement of the sound arm." In these latter movements, to which Raimiste's phenomenon belongs, two facts are important according to Walshe: "(1) in most cases of residual hemiparesis there is considerable voluntary power in the affected leg; and (2) it is impossible in these circumstances, and even in the normal subject, to adduct or abduct the extended limb without also bringing into action with equal force the corresponding muscles of the crossed leg."

We do not agree with Walshe's first remark, because we have seen Raimiste's phenomenon even when the leg has been completely paralysed. His second remark, however, is evidence that there is a certain functional connexion between the legs in symmetrical abduction and adduction, probably stronger than in other symmetrical movements of the legs.

Pathological Movements

On the other hand, involuntary pathological movements—e.g., parkinsonian tremors—can be checked, in some cases by voluntary or other synergic movements. Even tonic muscular spasm which cannot be inhibited voluntarily may sometimes be overcome by synergic movements—e.g., voluntary blinking inhibits oculogyric lateral rotation (Golmann, quoted by Astwazaturow 1929). The automatic upward rotation of the eyeball on blinking inhibits lateral rotation.

---

ptionally, in animals, both limbs of one side are advanced imultaneously, as in ambling.

the count will only approach this level after a large exchange transfusion. Thus a count of 5,000,000 Rh-negative cells per c.mm. *in the infant's circulation* could be achieved either by using donor's blood with a count of about 6,000,000 per c.mm. and carrying out an exchange of, say, 400 ml., or by using donor's blood *with a count of only 5,000,000 per c.mm., carrying out* an exchange of, say, 400 ml., and then injecting a *supplement of, say, 50 ml. of donor's blood*, without further withdrawal of blood from the infant.

It is clear that, though these are the factors which influence the concentration of Rh-negative cells in the infant's circulation at the end of transfusion, the concentration of Rh-positive cells remaining will depend on the infant's *initial* red-cell count and the volume of blood exchanged. Evidently the larger the volume exchanged the fewer will be the number of Rh-positive cells remaining.

Some of these effects are illustrated by the case reported above, where donor's blood with a red-cell count of 5,900,000 per c.mm. was used for an exchange transfusion in an infant with an initial red-cell count of 1,650,000 per c.mm. As an example, after the exchange of only 80 ml. of blood in this case, 65% of the cells in the infant's circulation were Rh-negative (see figure). According to a formula which only considers the exchange of blood in terms of volume (Wiener and Wexler 1946) this percentage exchange should only have been achieved after injecting and withdrawing an amount of blood equal to the infant's initial blood volume (probably a little over 200 ml. in this particular case).

Once an infant has been provided with a count of not less than 5,000,000 Rh-negative erythrocytes per c.mm., one can accurately predict the subsequent hæmoglobin levels by reckoning that 1% of the cells will disappear each day, and that the surviving cells will be diluted in a growing volume of plasma as the infant gains weight; an example has been given above. By the 30th day after transfusion the infant's hæmoglobin may have fallen to 60%, and it may subsequently fall a little lower. However, between the 30th and 60th days the infant's production of Rh-positive cells usually increases and no further fall in hæmoglobin occurs. Since the normal infant's hæmoglobin may fall to 70% between the 30th and 60th days values between 50% and 70% cannot be considered as very low, and it does not seem to be necessary to retransfuse infants at this stage unless the hæmoglobin falls below 50%.

Indications

The very mild course pursued by hæmolytic disease in all infants whose cord hæmoglobin was above 15 g. per 100 ml. and cord-bilirubin concentration below 3 mg. per 100 ml. and the stormy or fatal course pursued in infants whose cord blood showed anæmia or bilirubin values of over 4 mg. per 100 ml., has led us to conclude that the severity of a case of hæmolytic disease of the newborn can be assessed reliably from an examination of cord blood.

The value of examining cord blood for erythroblastæmia was stressed by Javert (1942), who also noted a slightly reduced hæmoglobin value and a considerably increased icteric index in a series of cases. Sadowski et al. (1947), who found bilirubin values between 4·9 and 8·1 mg. per 100 ml. in 3 severely affected infants, suggested that estimation of the cord bilirubin might be the best method of making an early diagnosis. Similarly, Pickles (1947) found plasma-bilirubin values between 3·0 and 7·5 mg. per 100 ml. in the cord blood of a series of affected infants.

We suggest that, if exchange transfusion is to be used as a method of treatment, it should only be carried out if the hæmoglobin of the cord blood is definitely below the normal range (say, below 14·5 g. per 100 ml.) or if the bilirubin value of the cord blood is 4 mg. per 100 ml. (normal range, say, 0·5–2·5 mg 100 ml.). When the hæmoglobin is only just below per 100 ml., or the bilirubin concentration is 3–4 100 ml., it is useful to examine a blood film. A excess of nucleated red blood-cells (say, more 10 per 100 white cells) should decide the issue in of an exchange transfusion. If cord blood has examined, the appearance of definite jaundice skin within 12 hours of birth in an infant whose gives a positive direct Coombs test is an in for exchange transfusion.

SUMMARY

There are three grounds upon which exchange fusion might be advocated for the treatment of hæmolytic disease of the newborn:

(1) To raise the hæmoglobin level rapidly increasing the blood volume. This might be in infants severely anæmic at birth, since found that these infants may have a raised pressure.

(2) To reduce to a minimum the amount of b of Rh-positive cells during the critical first of life, since it is possible that the blood d in this phase is indirectly responsible for the damage.

(3) To provide the infant with such a conce of Rh-negative cells by a single operation that no transfusions will be needed. In our experience proved to be a most substantial advantage. believe that, on this ground alone, exchange should receive widespread trial.

The percentage exchange effected by withdra infant's own erythrocytes and replacing Rh-negative erythrocytes depends on the infant's red-cell count and the donor's red-cell count on the total volume of blood exchanged. Thus, *infant is anæmic and the donor plethoric*, it easier to secure a good percentage exchange of and vice versa.

It is important not only to secure a good exchange of Rh-negative for Rh-positive cells to leave the infant with a high absolute con of Rh-negative cells to tide it over the period, which may extend to 40 days or more, which it is unable to maintain a satisfactory tion of Rh-positive cells. This objective is best by the use of donor's blood with a count of 5, 6,000,000 erythrocytes per c.mm.

The severity of a case of hæmolytic disease newborn can be assessed reliably from an ex of cord blood; some criteria are given.

A favourable impression has been formed clinical effects of exchange transfusion, but the of this treatment to lower mortality and mor must still be considered unproved. Meanwhile, we have not personally encountered any ill effects it, we consider that it can justifiably be used most convenient method of treatment available theless it is not a trivial procedure, and it should fore be reserved for cases where a single trans Rh-negative blood is not likely to suffice.

Most of the infants were treated in the obstetric de of the Postgraduate Medical School of London, but were treated in Kingston Hospital, and a few of the cases in St. Helier Hospital. We wish to thank the and nursing staffs of these departments for their Dr. L. K. Diamond, of Boston, for generous gifts of a and for supplying us with information about his te at an early stage of his own work; the donors of the Red Cross Society's Greater London Blood Transfusion and the North and South London Blood Supply De supplying Rh-negative blood at short notice.

an acid reaction. A trace of albumin be found in cases with much ascites lema of the legs. The stools may ne bulky, clay-coloured, and offensive.

thology.—Eggel (1901) found, in an sis of a series of cases, that 68% hepatomas and 32% arose from bile-duct epithelium (cholangioma); eas in Berman's (1941) series of 25 psies, 24 were hepatomas and 1 was olangioma, and in all cases micro- y showed cirrhosis of the liver.

Berman's series (1941) 57% had ahepatic secondary deposits—in the in 27 cases, and in the regional h-glands in 8. Metastases may be d in the ribs or the brain. Eggel) reports that 66% had extrahepatic stases, and that the spread may place along the lymphatics to the glands in the h, the upper part of the abdomen, or the thorax, ia the blood-stream by direct extension into the l and hepatic veins, giving rise to fresh growths e liver or to secondary deposits in the lungs. The cted series of children included 52 cases of hepatoma, 3 of cholangioma, 22 being unclassified. In 27% ese cases there were extrahepatic secondary deposits. *eatment* is purely palliative.

CASE-RECORD

boy, aged 15, born on June 4, 1930, volunteered with chool group for mass miniature radiography in March, and was recalled for a large film of his chest and for er clinical examination. I first saw him on April 11, when he was completely symptomless but admitted dull pain in the epigastrium six months earlier, which asted a fortnight and had not recurred. His weight was mary. He gave a past history of "influenza" in mber, 1945, but had recovered quickly from this.

examination.—He was thin but not anæmic. No ged glands could be detected in neck, axillæ, or groins. enlarged two fingerbreadths below costal margin; spleen alpable. A localised swelling in epigastric region moved the liver on respiration; it was hard and craggy, with egular and nodular surface. It was not cystic and did ulsate. Chest: grossly diminished breath sounds, with ushed vocal resonance over right lower lobe, anteriorly posteriorly; no adventitious sounds.

ysical signs of liver tumour suggested malignancy and patient was admitted to hospital.

vestigations (April, 1946).—Erythrocyte-sedimentation (E.S.R.) (Westergren) 126 mm. in 1 hour. Wassermann tion negative. Blood-count: red cells 5,181,000 per n.; Hb 92%; colour-index 0·9; white cells 4400 per m. (polymorphs 60%, large lymphocytes 8%, small phocytes 23%, large mononuclears 4%, eosinophils 5%). iography of chest (April 2, 1946) showed two large aded and clearly defined tumours in the anterior part of lower lobe of the right lung, suggesting hydatid cysts . 1 and 2). Rest of lung fields clear, with no evidence of ase.

dmitted to the Brompton Hospital on July 10, 1946, was febrile (temperature 100°F) and pale, with female s and gynæcomastia. There was a large slightly tender , moving with respiration, in the epigastrium, and the was much enlarged. Testes small: female distribution ubic hair. Poor air entry at right base of chest.

vestigations (July, 1946).—E.S.R. 140 mm. in 1 hour. d-count: slight hypochromic anæmia and a lympho- sis of 37%; Casoni test and Friedman test negative; ding and clotting times normal, and no abnormality utum. Radiography "showed an opacity in the right r zone situated anteriorly and also a rounded tumour he abdomen. It was suggested that, if the opacity in chest was intrapulmonary, hydatid disease should be idered, but primary mediastinal teratoma is the most y diagnosis." (L. G. B.)

iagnostic pneumoperitoneum suggested that the epigastric s was connected with the liver but not with the mass in lower zone of the chest on the right side.

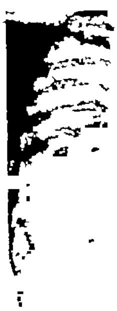

Fig. 1—Postero-anterior view (April 2, 1946) showing large round mass in lower lobe of right lung.

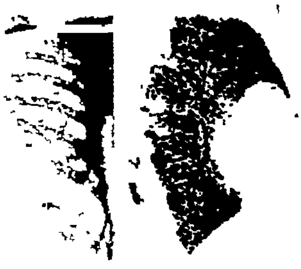

Fig. 2—Right lateral view (April 2, 1946) showing two rounded tumours situated anteriorly in lower lobe of right lung.

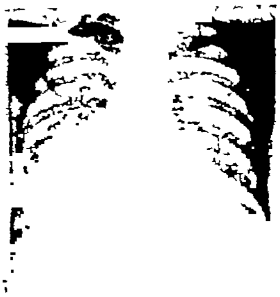

Fig. 3—Postero-anterior view (April 30, 1947) showing increase in size of tumour in lower lobe of right lung. Rest of lung field remains clear. Diaphragm is raised owing to enlargement of liver.

Aspiration biopsy of the mass in the abdomen produced tissue characteristic of primary carcinoma of the liver (hepatoma). Section was composed mainly of blood-clot. Tumour cells showed very considerable irregularity in shape and size and were closely packed together; some of them were binucleated.

Patient was referred for deep X-ray therapy, but this was ineffective and was therefore discontinued. He was discharged on Aug. 15, 1946, and the prognosis was considered hopeless.

Progress.—He remained symptomless and enjoyed good health but did not return to school. He spent a great deal of time motor-cycling and was leading an active life out of doors. His weight slowly increased, from 6st. 7¼ lb. on Oct. 31, 1946, to 6st. 10½ lb. on April 30, 1947.

In October, 1946, he had a short sharp attack of pleurisy on the right side, but quickly recovered. In November he was brighter and active, but had no symptoms apart from a recent gastric upset with vomiting and diarrhœa, and loss of 2½ lb. in 3 or 4 weeks. This weight was regained and at Christmas he felt very well, and was motor-cycling. At the end of April, 1947, however, he was much weaker, with anorexia and attacks of nausea and vomiting about once a week. He was now thin and apathetic, with no interest in his surroundings. He moved with difficulty, and it required great effort on his part to get on to the examination couch. The liver now almost filled abdomen, and the tumour in the epigastrium was larger and possibly slightly tender. A small amount of ascites was probably present.

Investigations (May 5, 1947).—van den Bergh and Fouchet's reactions negative. Blood-count: red cells 4,340,000 per c.mm.; Hb 68%; colour-index 0·79; hæmatocrit 34%; mean corpuscular volume 79·0 c.µ.; mean corpuscular Hb concentration 29·0%; E.S.R. (Wintrobe) 3 mm.; white cells 8200 per c.mm. (polymorphs 70%, lymphocytes 20%, large monocytes 9%)—a normocytic hypochromic anæmia.

The low E.S.R. is rather misleading in view of the malignant condition. Next day the E.S.R. was repeated by the Westergren method and was 120 mm. in the first hour.

Radiography of chest (April 30, 1947) showed that the secondary growths had not increased much (fig. 3).

The boy died on July 5, 1947, almost sixteen months after his first X-ray examination. Necropsy was refused.

COMMENT

There are several interesting features in this case: (1) The striking lack of development of male sex characteristics. (2) The misleading maintenance of body-weight, probably because the increase in size and weight of the liver balanced the obvious loss of flesh. (3) The long period before the development of symptoms, in spite of the two large secondary deposits in the lung. The first and single gastric upset appeared in November, 1946, seven months after his first clinical examination. It was not until April 28, 1947, a year after he was first seen, that he had regular attacks of nausea and vomiting at weekly intervals, and he died about two months later. (4) Comparison of the X-ray film of April, 1946, with that of April, 1947, shows that the two large secondary deposits had increased but slightly during the year.

DISCUSSION

If we consider the effect of restraint of the sound limb on automatic movement of the unsound limb, as already described, Raimiste's phenomenon, Walshe's second remark, and the fact that restraint of automatic arm-swinging on the sound side does not influence that on the unsound side in pyramidal lesions, we can conclude that restraint of either voluntary or automatic movements on the sound side elicits similar movements on the unsound side if those movements have been reduced or lost owing to a lesion of the motor tract (pyramidal or extrapyramidal) controlling those movements and when those movements are functionally connected.

Consequently the effect of such restraint is of diagnostic value where it is uncertain whether diminution or loss of movement is due to a pyramidal or to an extrapyramidal lesion. In pyramidal lesions, whether paresis of the arm is spastic or flaccid, restraint of the sound arm does not bring back the absent arm-swinging. Walshe (1921) found no sign of an associated reaction in arm or leg in flaccid paralysis, and concluded: "Some degree of hypertonus in a case of hemiplegia is an essential preliminary to the development of an associated reaction . . . the higher the degree of spasticity, the more forceful and the longer lasting will the associated reaction be."

In contrast to this, the absence of pronounced hypertonus in extrapyramidal lesions is a necessary condition to enable restraint of the limb on the sound side to bring back movements in the limb on the unsound side.

Most workers consider that the disappearance of arm-swinging represents a primary disturbance. There is no doubt that hypertonus also impedes these movements. Froment and Gardère (1921) consider that even in cases without evident hypertonus there is latent rigidity. Noica (1936) holds the same opinion and says that, where arm-swinging has been lost and yet hypertonus is not evident, hypertonus will develop later, at first only in walking and only in the proximal parts.

The fact that arm-swinging can disappear in unilateral pyramidal lesions with minimal paresis and no evident hypertonus might be regarded as supporting Wilson's (1928) opinion that arm-swinging is not purely automatic. But against this assumption is the observation that, in unilateral parkinsonism, deliberate swinging of the unsound arm inhibits arm-swinging by the sound arm. This harmonises with the fact that, in normal people, automatic movements are inhibited by attempts at voluntary control, and with our observation that, in unilateral parkinsonism, deliberately increased arm-swinging on the sound side does not affect arm-swinging on the unsound side.

These investigations cannot be regarded as complete. It would be especially interesting to study cases of post-concussional Mann's syndrome. In unilateral cerebellar lesions Wartenberg (1930), Marburg (1936), and Holmes (1946) find that arm-swinging disappears, whereas Grinker and Levy (1943) seem to think that it increases because of hypotonus. In a patient with a bilateral cerebellar lesion, more pronounced on the left side, we found that arm-swinging was diminished on the left side and that when the right arm was restrained arm-swinging increased in the left arm.

SUMMARY

Restraint of automatic arm-swinging on one side in normal people reinforces arm-swinging on the opposite side.

Restraint of arm-swinging on the sound side in unilateral extrapyramidal lesions—e.g., incipient parkinsonism, chorea minor, and encephalitic pseudo-neurasthenia—brings back the arm-swinging on the affected side if there is not much hypertonus.

In unilateral pyramidal lesions such restraint such effect, regardless of the state of muscular tone.

This test is of diagnostic value where it is de whether loss of arm-swinging on one side is due pyramidal or to an extrapyramidal lesion.

PRIMARY CARCINOMA OF THE L

IN A BOY AGED 15

A. E. Beynon
M.R.C.S.
MEDICAL DIRECTOR AND PHYSICIAN, CHEST RADIOG
CENTRE, NOTTINGHAM

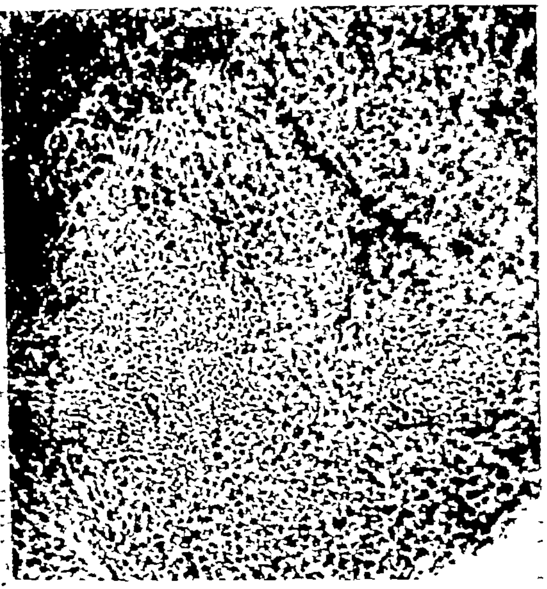
The ratio between primary and secondary c of the liver has been estimated as between 1: 1 : 40. In 18,500 necropsies at Guy's Hospital (White 1908) 24 cases (0·13%) of primary car of the liver were found, and the incidence in necropsies at the General Infirmary, Leeds (1922) was the same. Data from several Ame European hospitals revealed 144 cases (0·21%) in necropsies, and reports collected from Asia and give 416 cases (1·05%) in 39,701, and from a hospital 134 cases (0·76%) in 17,664 necropsies. (1940) estimates that primary carcinoma of the over forty times more frequent in some of the p races than in the European.

The disease occurs mostly in or after mi and is said to be rare before 40 years of age. recorded case was in a baby girl aged 5 weeks (1912). Berman (1940), in a series of cases in natives, found that 82·6% of the patients were of age or less, while the highest incidence was age-group 21–30. Steiner (1938), in a critical of the literature, found 77 proved cases in up to 16 years of age, 53% of them in children the age of 2 years.

This disease is seen more often in men than in and of affected children Steiner (1938) observed 68% were boys.

Symptoms.—There are no characteristic sym Dull pain is a frequent feature and is referred to liver region. *Usually there are* gastric upse anorexia, nausea, vomiting, diarrhœa, or consti Jaundice and ascites are uncommon. The a duration of life after the onset of symptoms is months. No recovery has yet been reported. incidence of symptoms in Berman's (1940) 42 cases abdominal pain in 90%, asthenia in 86%, and d especially on exertion, in 26%; but this was a symptom.

Physical Signs.—Most patients do not lose before admission to hospital but when bedridden weight rapidly. The liver is always enlarged and t Jaundice was noted in 43% and ascites in 55% cases (Berman 1940). Dilated superficial abdominal and œdema of the ankles and legs are found commonly, and hæmatemesis rarely. Usually the perature is either normal or subnormal, but *some* pa are febrile. The urine is unaffected in the early but later is diminished in amount and of high



1—Liver-biopsy specimen showing focal granulomatous lesions. (× 95.)

lers containing beryllium were prepared, ground, and ed in his laboratory, only a few feet from his bench. undoubtedly increased the risk to which he was exposed. r December, 1942, his contact with phosphors was gible; for the next two years he worked in other rooms only occasionally chanced to walk through the laboratory. November, 1945, three years after his last significant sure, he had a feverish cold, and a dry cough developed n he returned to work three days later. After another th the cough became productive, yielding a little yellown sputum, and he began to be dyspnœic on exertion; ould neither run for a bus nor climb a hill. At the same he began to lose weight rapidly, and by February, , was already 23 lb. below normal. Radiography of his t then led to a tentative diagnosis of miliary tuberculosis. could walk only about 30 yards on the level. He was itted to hospital, where miliary tuberculosis was excluded pulmonary sarcoidosis diagnosed. All of many sputum minations were negative for tubercle bacilli; a Mantoux at 1:1000 dilution was positive; and a blood-count wed 6,000,000 red cells per c.mm. and Hb 130%. The ient continued to be seen at various hospitals for a year and alf after his discharge. During this time his weight was still ing, his appetite was poor, and he had to be absent from rk repeatedly because of attacks resembling acute bronitis. His chief symptom, which varied in severity, was ays dyspnœa on exertion and at rest.

n examination in February, 1948, I found that he weighed ly 7 st. 5 lb., having lost 51 lb. in all. He was dyspnœic rest and slightly cyanosed, but there was no clubbing of fingers. The cardiovascular system was normal except an accentuated second heart sound in the pulmonary a. The chest expansion was only 1 in. The percussion te of the chest was resonant, but multiple rhonchi and rse crepitations could be heard in all areas. The liver edge s palpable 1½ in. below the costal margin, but the upper it of hepatic dullness in the chest was displaced downwards. e spleen was not palpable, and only one small lymph-gland s felt in the neck. No glands were discovered elsewhere, l the parotids and uveal tracts were normal.

He was again admitted to hospital. During a stay of three ks there was no fever, but the respiratory-rate at rest ied remarkably, between 18 and 38 per min. On the htest exertion he was dyspnœic to the point of distress.

ital capacity: 1470 c.cm. A healthy man of this patient's ght and weight might have had a vital capacity of 3800 m., calculated from surface area by the formula of West 20). The capacity recorded was only 39% of this.

Sputum: repeatedly negative for *Myco. tuberculosis*.

Erythrocyte-sedimentation rate: 7–13 mm./1 hour (Wintrobe).

Mantoux test: 1/10,000 negative and 1 1000 negative.

Blood-count: Hb 112%, red cells 6,412,000 per c.mm., white cells 5300 per c.mm. (polymorphs 44%, eosinophils 1%, lymphocytes 45%, large hyaline cells 10%).

Electrocardiogram: some right ventricular preponderance.

Circulation-time: arm to breath (ether min. 5) = 7–9 sec., arm to face (histamine phosphate 0·1 mg.) = 25–28 sec.

Glucose-tolerance test: within normal limits.

Liver-function tests: van den Bergh, indirect reaction 0·5 mg. bilirubin per 100 ml. Alkaline phosphatase, 6 units. Thymol turbidity, 6 units. Cephalin cholesterol flocculation, 1. Serum colloidal gold, 0.

Plasma-proteins: total 6·6 g. per 100 ml. (albumin 4·4 g. and globulin 2·2 g. per 100 ml.)

Beryllium in urine (spectrographic technique): on admission, nil detected. After a course of dimercaprol (BAL), nil detected.

Radiography: X-ray films of the patient's hands and feet in April, 1946, and April, 1948, showed no abnormality.

Radiography of his chest four months after the onset of his illness showed a fine punctate or granular marking scattered throughout both lung fields, the lesions being 0·5–1·0 mm. across. The cardiac outline was normal. Eight months after the onset there was a similar uniform fine punctate marking, with some evidence of a reticular pattern. Seventeen months after the onset there was more definite appearance of reticulation in all areas with some small scattered nodules, 2 mm. across, at the periphery of the mid-zones. The right interlobar septum had been drawn upwards. There was broadening of the upper half of the cardiac shadow, especially in the region of the pulmonary artery; the hilar vessels were prominent. Twenty-one months after the onset more definite fine nodulation was apparent in the upper mid-zones, though the other appearances were unchanged. Thirty months after the onset there was some clearing of the lower zones, where the appearances suggested emphysema. In the upper and mid zones there was a coarse reticular pattern with much increase of linear striæ, suggesting fibrosis; nodulation was less in evidence. The diaphragm was flattened in the shape of a cone, the mediastinal shadow was broad, and the hilar vessels were very prominent. There was no enlargement of the left auricle on screening in the oblique positions with barium emulsion in the œsophagus.

Drill biopsy of liver showed focal granulomatous areas scattered throughout the tissue. These areas consisted mainly of macrophages and small round cells, with a few fibroblasts and occasional epithelioid cells, but no giant cells. There was no necrosis or fibrosis. The surrounding liver parenchyma was normal (figs. 1 and 2).

Ultraviolet microscopy showed aggregates of sharply defined spiculate particles with a bright white fluorescence in the middle of some of the granulomatous lesions. These were seen only in the abnormal tissue. In specimens of normal liver obtained from necropsies and examined by this method,

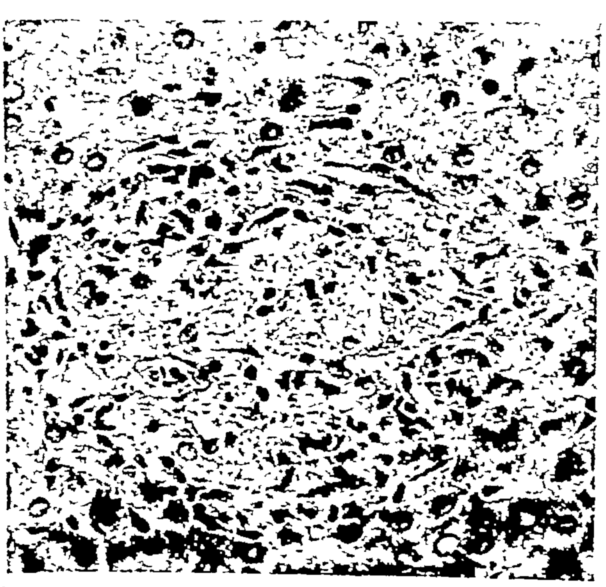


Fig. 2—The smaller of the two granulomatous lesions shown in fig. 1. (× 450.)

(5) The absence of icterus throughout, both clinically and by van den Bergh reaction.

SUMMARY

A case is reported of primary carcinoma of the liver detected in a schoolboy aged 15 by a mass miniature radiography unit.

Radiography showed two clearly defined tumours in the lower lobe of the right lung. The rest of the lung fields was clear. An apparently malignant tumour of the liver was found on clinical examination. Aspiration biopsy confirmed the diagnosis.

The boy led a normal symptomless life for about a year, but then his condition rapidly deteriorated, and he died about sixteen months after the original radiography. There was no jaundice, and the metastases in the lung increased but slightly.

I wish to thank Dr. T. H. Gillison, of Ilkeston, Derbyshire, for his keen coöperation and the case-record; Dr. W. D. Brooks for allowing me to quote the findings while the boy was under his care in the Brompton Hospital; and Dr. L. G Blair for the radiological reports.

DELAYED PNEUMONITIS IN A BERYLLIUM WORKER

REPORT OF A CASE

JOHN N. AGATE
M.A., M.B.,Camb., M.R.C.P.
From the Department for Research in Industrial Medicine (Medical Research Council), the London Hospital

RECENT reports from the United States show that the handling of beryllium compounds is attended by a risk of dermatitis or of respiratory disease. This had already been discovered by Weber and Englehardt (1933) in Germany; and Gelman (1936) in Russia, and Marradi Fabroni (1935), experimenting with animals, had suggested calling the lung disease "berylliosis," but no reports appear to have come from Europe since 1943. American writers have lately helped to clarify the clinical picture, and to some extent the pathology, of these diseases as they affect man. Nevertheless, some of the ætiological factors have still to be discovered.

In the 'twenties and early 'thirties negligible quantities of beryllium compounds were used in the United States, but during and since the late war the consumption has risen steadily, and with it the incidence of these occupational diseases. Two of the principal industries now concerned are those in which fluorescent lamps and copper alloys are made. To supply them, several factories have been engaged in extracting beryllium from ore, and it was here that the hazards were first encountered.

In Great Britain the use of beryllium has lagged somewhat behind, especially in war-time, for reasons of expediency. A few of the compounds, however, have been used experimentally here from about 1936 onwards. Developments in the British fluorescent lamp industry have been rapid of late, and the commercial use of the phosphorescent powders which contain beryllium has already begun. The more this element is used in this country, the more likely are we to have to share the American experiences of its toxicity.

Van Ordstrand et al. (1943) described "chemical pneumonia" in 3 men extracting beryllium oxide from ore. The disease came on soon after exposure, was acute, and was characterised by cough, mild pyrexia, and dyspnœa. Van Ordstrand et al. (1945) reported 38 similar cases and 90 others of nasopharyngitis and tracheobronchitis; most of these came from the industry, but in some there had been exposure and fumes in the preparation of pure be and the making of beryllium-copper alloys. 5 deaths.

Hardy and Tabershaw (1946) described, as a clinical entity, "delayed chemical pneumoni occurrence of 17 such cases in one fluo factory in Salem, Massachusetts, suggested phosphorescent powders used there were to the one chiefly handled was a mixed silicate beryllium, and manganese. There were 6 deat important series, and several survivors were left incapacitated. Pascucci (1948), in a later f which also included 15 fresh cases, reports of the patients have died and 30% are still The remarkable feature was the delay between to risk and the appearance of symptoms. In one the interval was three years. Wilson (1948) s the delay may be as long as six years.

In September, 1947, an exchange of info the Sixth Saranac Symposium of the Edward Foundation, Saranac Lake, N.Y., indicated that any of the beryllium compounds in use in indu be handled with absolute safety. The soluble sal as sulphate, fluoride, and oxyfluoride, had already held responsible for the dermatitis and for much of acute respiratory disease (Gelman 1936 and workers). But fresh evidence now suggested that of both acute and delayed respiratory disease had from working with beryllium compounds, solu insoluble, in most of the industries concerned. most but not all of the acute cases had come factories where beryllium oxide was extracted fro whereas *most but not all of the delayed* cases had from the lamp industry. Recent or past expos beryllium compounds was the one factor com all the many cases then under discussion. The also reason to think that certain people were un susceptible, for "neighbourhood cases" were d in which the victims could only have been ex very slight risk, because they lived close to fact had never been inside them. The diagnosis in least of such cases was supported by necropsy

Gardner (1946) had already estimated that the of authentic cases of delayed pneumonitis was 60. referred to typical cases from the radio-valve neon-sign industries besides those already mentio

Stimulated by these accounts and by the lack of reports from the United Kingdom, I began to inquiries in some British factories, and was soon a man who had once worked with beryllium comp and who was now said to be seriously incapacitated b "sarcoid." Further investigation suggested that his was one of delayed pneumonitis as just described; may be the first to have occurred in Great Britain.

CASE-RECORD

A physicist, aged 30, was engaged in research on fil and mercury-vapour lamps from his graduation in until 1941. He was slightly exposed to dust between *and 1941, when he was filling some 200 lamps* with pow sulphides of zinc and cadmium. He noted no ill effects this. Between December, 1941, and December, 194 worked on the development of tubular fluorescent He handled about *500 tubes, which had* already been internally with the phosphorescent powders containing beryllium manganese silicate and magnesium tun He had to clean the last 3 inches of each tube with a du from time to time he shook out the *duster and* a cloud of arose. The next stage—the sealing-in of electrodes exhaustion of the tube—was not without risk, because sometimes had to suck at a side tube, and could have in powder. He was working in a small *laboratory*, but the co processes were all done in a separate room. During Oc and November, 1942, small quantities of these ph

egree of exposure needed for this dust to cause harm
ich less than that usually needed to bring about
ational pulmonary disease. Cough, dyspnœa, and
ne loss of weight were the chief clinical features.
graphy revealed extensive bilateral pulmonary
e. Granulomatous lesions were found in the liver
ut biochemical evidence of liver disorder.

commercial use of beryllium has expanded so
in the last three years that further cases may be
ted in Great Britain. If the onset of the disease can
layed as long as six years, the ætiology may not be
cted unless an adequate history is taken of the
nt's occupations.

here possible, substitution of other compounds in
of those of beryllium is clearly the best preventive
ure. In processes where this element must still be
vigorous suppression of all dust and fumes, and
ar medical supervision of workers are necessary.
prognosis of this disease is poor and treatment
ctual; the disability that is left, as in the present
may be serious and permanent. Legislation to
de for compensation might perhaps be considered
before the occurrence of any *extensive outbreak of*
in Great Britain.

ish to thank Dr. Donald Hunter, director of the Depart-
for Research in Industrial Medicine, for his encourage-
and advice; Mr. Frank Ellis for performing the liver
; Dr. James Maxwell for allowing me access to the
t and his earlier radiograms; Dr. P. L. Bidstrup and
Garrad for their assistance; the staff of the Bernhard
Institute of Pathology, London Hospital, for their help;
Mr. G. Smailes and Mr. F. V. Welch, of the National
ute for Medical Research, for the photomicrographs.

. . Many thousands of hours of the time of the school
cal officers and nurses have been lost due to our failure
ke the family as the unit. In all our work the golden
would be to do what is best for the family, for instance,
e question whether the child should attend a nursery
l should be judged on its merits—in some cases the
y life would be benefited by a child attending, in others
the reverse. The pros and cons must be measured
he individual child and family. With the exception of
parents with diseased minds who are deliberately cruel;
most any cost, the family should be kept together.
e must intensify our efforts to help the problem families
ir own homes, as is done by the Family Service Units.
must teach the mother—this does not necessarily mean
ing her—we must help her by showing how she could
ge better in her (perhaps) poor home, use the existing
n range and the defective tools with which she has
her jobs; or perhaps she may need help and rest
a rehabilitation centre, such as Brentwood, can give,
she may take her children and where she will be taught
raft in the right way, by the right people, and be
ready to make a fresh start. Our aim must be to
ure the mother'—to use the greatest force in the
, mother love. If we teach the mother rightly she will
e job of teaching the children for us, and we must
mber that the teaching she gives goes on all the time."

Reviews of Books

Treatment of Heart Disease

WILLIAM A. BRAMS, M.S., M.D., PH.D., associate professor of medicine, Northwestern University, Chicago. London: W. B. Saunders. 1948. Pp. 195. 17*s*. 6*d*.

WRITING as a practical clinician, and basing his work upon his own experience, Professor Brams has produced an excellent textbook. Dogmatic without being intolerant, comprehensive yet never diffuse, he gives the medical student and the general practitioner the information they need for dealing with patients with heart disease. One of his great merits is that, unlike many writers of textbooks on therapeutics, he has restricted himself to his subject and avoided unnecessary discussions of clinical and diagnostic problems. A long first chapter on the "pharmacologic action of drugs used in the treatment of heart disease," saves much unnecessary repetition in the sections dealing with individual disorders.

Major Endocrine Disorders

(2nd ed.) S. LEONARD SIMPSON, M.A., M.D., F.R.C.P., physician, Willesden General Hospital. London: Oxford University Press. 1948. Pp. 552. 42*s*.

THIS is not a textbook of endocrinology: and indeed there is no reason why it should be, except that no British author has yet attempted to write one, which is perhaps a pity. Since he is not writing a textbook, Dr. Simpson is under no obligation to give a carefully balanced account of the subject, with much space for the common or important aspects, and little for rarities, museum pieces, or details of tests performed in this country by perhaps no more than a score of specially trained experts. Instead he treats the specialty from the personal point of view, emphasising aspects in which he is specially interested, such as the adrenal cortex. Other aspects—such as recent work on the œstrogens—in which he has no particular interest are treated summarily and with less care for accuracy. It is as though he had set himself to clarify his own views by putting down the product of his own clinical experience and of his wide reading of the literature. Unless the reader appreciates this personal approach he may be slightly irritated by the frequent use of the first person singular. The autobiographical exposition, however, has advantages as well as disadvantages. Dr. Simpson has taken an active interest in endocrinology for many years, and this account of his experience represents very fairly the views of an enlightened physician who keeps abreast of recent advances in the subject. Though it is a second edition, the book has been virtually rewritten and is now at least four times as big as it was in 1938. There are many excellent illustrations and the standard of production is high.

Surgical Treatment of the Abdomen

Editors: FREDERICK W. BANCROFT, M.D., F.A.C.S., professor of clinical surgery, New York Medical College: PRESTON A. WADE, M.D., F.A.C.S., associate professor of clinical surgery, Cornell University. Philadelphia and London: J. B. Lippincott. 1947. Pp. 1026. £5 10*s*.

THIS large, and in many ways admirable, American textbook of operative surgery has a misleading title. It includes sections on anæsthesia, on the principles of surgical treatment, and on the mouth and œsophagus; but it does not cover the abdomen completely, because the urogenital systems, male and female, are not considered, nor is the abdominal wall. This may perhaps be because it is one in a series of volumes on operative surgery; but it means that the surgeon who wants information on nephrectomy or the treatment of hernia will not get it here. The section on anæsthesia seems too short for the specialist anæsthetist and too theoretical for the man who is compelled by circumstances to administer an anæsthetic and who wants information on how to do it. The chapters on local and regional anæsthesia, however, will be useful to the general surgeon. The section on general topics carries an excellent chapter on the fundamental principles of surgical technique, by Stevenson and Reid, but elsewhere is inclined to give single fluorescent bodies were sometimes seen in the sinusoids and small aggregates in the region of the portal vein, but these bodies were rounded and often had a yellowish tint. Possibly the particles within the lesions in the present case consisted of the original fluorescent powder, but the test cannot yet be considered conclusive.

Progress.—The patient has not improved at all since his admission to hospital. He is remarkably dyspnœic, can do light laboratory work, but is often absent as a result of minor respiratory infections which drive him to bed.

CLINICAL PICTURE

Hardy and Tabershaw (1946) originally reported 17 cases from one factory. Since then, others have occurred there, and men and women engaged in all the stages of fluorescent lamp making have been affected. The original 17 were variously exposed to zinc beryllium manganese silicate for from 5 months to 5 years. The present patient was exposed to just the same risk for a year, and there was a delay of 3 years before his first symptoms appeared; this is also in keeping with the other cases. Hardy and Tabershaw observed that loss of weight at the onset, dyspnœa on exertion, cough, and fatigability were present in nearly all their patients. They wrote of weight losses of 20, 34, and even 40 lb. within the first year of illness. Adventitious sounds were heard in the chest in 13 of their cases, tachycardia was present in 10, and an accentuated pulmonary second sound in 6, and an abnormally high resting respiratory-rate was found in 10 out of the 11 cases in which it was recorded. The liver was enlarged in 2 cases, and the spleen in 2. In only 2 patients could adenopathy be found, and in 2 there were skin lesions which later proved to be granulomatous. The clinical findings in the present case agree very closely. Though anorexia was not an outstanding symptom, weight loss, dyspnœa, and cough were; indeed, the patient had lost 23 lb. in the first three months, and 51 lb. within 2 years. He had no generalised adenopathy and no splenomegaly, but the edge of his liver was palpable, and a biopsy specimen contained granulomatous lesions. Hardy and Tabershaw refer to one necropsy in which granulomatous tissue was found in the liver, lungs, and hilar glands, and Hardy (personal communication 1947) found similar granulomata in liver-biopsy material from a later case.

The radiographical appearances in Hardy and Tabershaw's series of cases were described (by Wilson and Sosman) as being in three stages: (1) "granularity," (2) a superimposed reticular pattern, and (3) nodulation. The appearances in the present case do not correspond exactly to these stages; for, though there are signs of "granularity" and reticulation, the nodular stage is less pronounced than in some of the original films which I have seen. However, Wilson (1948) now allows that not all cases progress in the three stages originally described, and he adds a further stage of coalescence of lesions in the upper zones, with emphysema at the bases, just as was seen in the later films in the present case.

The chronicity of the disease in this case, and the serious residual disability, are typical of many. In short, there appears to be a sufficient resemblance between this case history and those of others who had delayed chemical pneumonitis to justify making the same diagnosis. Consequently, the disease must be attributed to the patient's former occupation.

DIAGNOSIS

The present case was first tentatively diagnosed as one of acute miliary tuberculosis on radiological grounds; later it was called Boeck's sarcoidosis. This is of interest because these diagnoses were made at first in the earliest American cases. Indeed it was only when a number of alleged cases of "sarcoidosis" occurred together in one factory that this diagnosis was questioned occupational ætiology suspected.

Miliary tuberculosis may be excluded by the of the typical pyrexia or other evidences of a gro process, and eventually on the course of the The resemblance to Boeck's sarcoidosis, ho undeniable, and a differential diagnosis may easy to make, particularly since both disease granulomatous hepatic lesions. Schaumann (Nickerson (1937), van Buchem (1946), and oth described these lesions in necropsy material from of sarcoidosis, and Scadding and Sherlock (1 found them in biopsy specimens.. In the pre the radiographical appearances also could hav taken for those of pulmonary sarcoidosis, though latter disease there is usually a contrast between subjective symptoms and the grossly abnormal findings (Reisner 1944). Moreover, in the pre there were no skin or ocular lesions, no ad and no abnormalities of salivary glands or of the loss of weight was remarkably severe, and t weakness, tachypnœa, and a residual disa greater than would be expected in sarcoidosis clinical features therefore make the latter unlikely, and a positive Mantoux reaction is and normal radiograms of the extremities are evidence against it.

Finally, there is the histology of the granulom the liver, in which there is pleomorphism and th consist main [illegible] and fibroblasts, considerable [illegible] but no giant In the lesions of sarcoidosis it is usually reported the cells are mostly epithelioid cells, with giant but with less round-cell infiltration.

The other differential diagnoses to be considered generalised carcinomatosis, the pulmonary mycoses, the pneumonoconioses. The last-named could be exc by the occupational history. The acute pneum beryllium workers, too, is differentiated by the its onset, which is never much delayed, and by that it usually resolves satisfactorily if the p given rest and removed from exposure. Valvul disease with failure may be suggested by the c dyspnœa, and radiographical appearance of the but in the present case the other typical sig absent.

The urine of this patient contained no beryllium when tested by the most sensitive method known. however, more than 5 years had elapsed since his exposure, it is reasonable to assume that any ber not fixed in the tissues would have been excreted before. The total absorption is unlikely to have ex a few milligrammes.

This disease always presents clinically as one affects the lungs, but granulomata have also been det in liver, glands, and skin; hence the pulmonary l appear to be only part of a more generalised patholo condition. Experiments on animals may event explain the process involved. It is of interest to spe whether beryllium compounds elicit this respon direct action or by sensitising the tissues to some o agent. In some respects lung diseases due to beryl resemble infections. On the other hand, Grier e (1948) have described granulomata in the skin cuts from broken fluorescent lamps; these granulo contained epithelioid cells and giant cells, and in case beryllium was detected in excised tissue.

SUMMARY AND CONCLUSIONS

A laboratory worker developed a chronic pneumon three years after exposure to a phosphorescent pow (zinc beryllium manganese silicate) used in mak fluorescent lamps. The patient inadvertently exp himself to risk, for it is not generally understood t osed of water, this means that there will be a pondingly greater absorption of energy by the s. The local heat produced in the body by this of energy brings about an increase of venous return a vasodilatation through local reflex mechanisms lirect metabolic effects. The heart-rate may be ased by speeding up the generation and propagation pulses through the sino-auricular node. On the of the experimental tests, the Mayo Clinic have carrying out clinical studies with microwaves for ast year.

NEUROSURGICAL SERVICE

their new organisation by regions, the British tal services form a clear pattern, in which each ent gathers strength from, or gives support to, its bours. Even so, there are still dangerous gaps, ularly in the services which are least often called r most difficult to supply; and perhaps the most le of these is neurosurgery.

e Society of British Neurological Surgeons, like the ty of Thoracic Surgeons,[1] has produced its own n for the future[2]; and this shows how pitifully ent are the present resources. The expansion of surgical work, like that of chest surgery, has been ; and this means that there are neither enough tal beds nor enough trained surgeons. The late brought a great increase in the number of beds side for this specialty; but even now large areas no neurosurgical centre whatever. The report sts that the aim should be to supply for every on people a centre having 50–60 beds (though some that 80–100 are needed). The regions named as ally needy are South Wales, the eastern counties, land. Northern Ireland, and London; and in tion area centres, with some 25 beds each, are osed for the East Midlands, the East Riding of shire, north Lancashire, and the south-west. New res, says the report, should be placed on land shared a teaching, or at least a general, hospital. For se of resources, convalescent beds should, if possible, the same hospital; but, if this advantage can be only by the exclusion of the whole unit from the ral hospital, then it should be foregone. The mittee, insisting that surgical neurology is a proper ject for the undergraduate's clinical training, holds t units of not less than 25 beds should be installed aching hospitals.

onsiderable thought has been given to the training future neurosurgeons. This, in the committee's view, uld be in two stages. The first is that of general ining in which the young graduate spends a year in ior resident appointments, a second year in whole- e study of the basic sciences, and a third as senior se-surgeon or R.S.O. After taking the F.R.C.S. he will, report points out, become a better recruit by doing other year in general surgery. "We say this from the owledge that the best and most telling experience in neral surgery is not usually to be had until this loma has been acquired." The second stage—that special apprenticeship—would take at least a further r and a half years, the trainee spending a year each work as senior house-surgeon in neurosurgery; in urophysiology or an alternative subject (including months in medical neurology); in neurosurgery as egistrar; and finally as a registrar with work outside hospital as a domiciliary consultant.

Not all neurologists, and perhaps not every neuro- geon, will agree with the committee in maintaining t head injuries should necessarily be treated in the gical unit. In the late war the largest Service hospital for medical and surgical neurological cases adopted the practice of admitting all closed head injuries to the medical wards. The virtue of this arrangement was twofold: it saved surgical beds; and from the start of treatment these cases were in the hands of the physicians, whose interests perhaps qualified them better to take charge up to and including convalescence. The occasional intervention by the surgeon—for example, to make a burr-hole—which is cited as a reason for surgical control, was seen as an incident in a disorder which was essentially medical; and, since the committee visualises medical and surgical units working side by side in a single specialised department, there seems to be no practical reason why this view should not prevail in the future. The further contention that few physicians have displayed much interest in head injuries should make neurologists look to their laurels.

WAR RESEARCHES ON THE CORNEA

SOME of the work undertaken for urgent reasons during the war is only now being published. Two monographs appearing within the last few months describe investigations, by teams in the United States and in England, on the mode of action of war gases on the eye.[1] Both reflect the high academic standard of research favoured by the Allied policy of employing civilian scientists to study Service problems. Though largely concerned with the effects of substances unlikely in ordinary circumstances to come in contact with the eye, the thirteen authors have done much to set knowledge of the biochemistry and histopathology of the cornea on a sounder basis. The Americans directed their attention mainly to biochemistry, and the English mostly to cellular reactions; but both groups start with fundamentals applicable to the study of any chemical injury to the cornea. They point out that the action is determined not only by the toxicity of the material, but also by its physical power of penetration. They emphasise the importance of SH groupings in reaction with proteins, and by bringing the problem of injury into the realm of enzyme inhibitions and activations they have advanced ophthalmic pathology far beyond its previous boundaries.

The metabolism of the cornea has been studied in great detail. The functions of its various layers have been separated. Attention has been drawn to such phenomena as the inability of the stroma to take up oxygen or to utilise lactate or pyruvate, the great capabilities of the epithelium, and the existence of a hydrogen transport system from stroma to epithelium. The epithelium-stroma boundary, probably a protein-lipoid multilayer, is the seat of many important activities, and the circumstances in which the epithelium becomes loosened have been carefully examined. Oxygen is essential for this loosening, which does *not* occur anaerobically even after poisoning of enzyme systems with various toxins. The effects of chemical and physical agents (e.g., mustard gas, colchicine, ultraviolet light, and X rays) on the mitosis and on nuclear fragmentation have also been worked out, and so have the effects on the stroma and epithelium of a large number of chemicals not related to war.

The English team, who began work nearly three years before the Americans, gave its attention largely to the clinical appearances of chemical injuries and to the histology of various types of healing. The problem of avascular healing of the corneal stroma and of the epithelium has puzzled ophthalmologists for many decades and the experiments described in the *British* too much detail: it is doubtful, for example, whether the 4 pages illustrating technical apparatus for serum drying are worth their room in a book designed for practising surgeons. The section on the mouth and œsophagus is notable for J. H. Garlock's article on the œsophagus; and the magnificent section on the abdomen, occupying two-thirds of the book, contains chapters by men as well known in England as in America—R. Schindler, A. W. Allen, F. W. Rankin, A. O. Whipple, and others. Perhaps the best chapter in the book is by the late Roscoe Graham on the surgery of the stomach and duodenum: its wisdom, lucidity, and illustrations will commend it as much to the expert in gastric surgery as to the novice.

Nouvelles techniques des traitement de fractures

H. GODARD: R. MICHEL-BECHET. Paris: Doin. 1948. Pp. 406. Fr. 1500.

THIS book gives a full account of recent Continental methods of fracture treatment, which make use of a variety of ingenious mechanical aids to reduction, and various wires or nails of the Küntscher type. Initial chapters describe animal experiments carried out by the authors, which seem barely to prove that the medullary nail is harmless: but the results they record from their practice seem to justify a freer use of the method than is usual in this country. For any surgeon starting to employ it, this book (if it can be obtained) can be strongly recommended, for the authors describe their techniques for almost every fracture of the body with much detail and clarity. They also give full references to other methods of treatment, and in many cases their preference is for the more conservative methods. Far from being rabidly biased in favour of novelty, the book appears to be an earnest account of the methods which the authors, who obviously have great experience, find to give the most satisfactory results.

Hodgkin's Disease and Allied Disorders

HENRY JACKSON, Jr., M.D., assistant professor of medicine, Harvard Medical School; FREDERIC PARKER, Jr., M.D., associate professor of pathology in the school. New York and London: Oxford University Press. 1947. Pp. 177. 45s.

A SPATE of writings bears witness to the fascination which Hodgkin's disease continues to exert. The most recent addition is this monograph from the Harvard Medical School, in which Professor Jackson and Professor Parker analyse a series of cases. Knowledge of the causation of these diseases has not advanced; their clinical and pathological descriptions make no fresh contribution to the mass of factual data already accumulated, a review of which they do not attempt; and they essay no interpretation and offer no general notions to clarify our ideas. Thus it is to their views on the relations between lymphadenoma and allied disorders that their monograph owes its chief interest.

From the diseases which declare themselves by enlargement of lymph-nodes, they have selected three for particular consideration: Hodgkin's disease itself, which they prefer to call Hodgkin's "granuloma"; a condition they have named "Hodgkin's paragranuloma"; and a true neoplasm, Hodgkin's sarcoma. The novelty of "paragranuloma" lies in the term itself, and the authors' apologetic explanation leaves the reader uncertain whether it is intended to convey a close relationship to Hodgkin's disease, or to granulomata in general. Its histological pattern is familiar to workers in this field, and has been given the descriptive title of lymphoreticular medullary reticulosis by Robb-Smith, whose views are accorded no mention in this monograph. "Hodgkin's sarcoma" was employed by Ewing twenty years ago to describe some of the polymorphic neoplasms of lymphoid tissue. The interest of Jackson and Parker's observations lies in their claim that, although Hodgkin's "paragranuloma" commonly pursues a leisurely and relatively benign course, in about one-fifth it is transmuted into the more rapidly progressive "Hodgkin's granuloma." A like transition may occur, they believe, from granuloma to sarcoma. They see Hodgkin's disease as a disorder in which there are three histological varieties, and though either of the more benign may run its course unchanged there is a tendency with the passage of for it to ascend the scale of malignancy.

There is nothing new about the idea of a change granuloma to sarcoma; Ewing believed that "H sarcoma" might originate in this manner, though experienced histologists are still unwilling to ac metamorphosis. That "paragranuloma" might into "granuloma" has not been suggested perhaps because the "paragranuloma" is not g recognised. There is a practical importance in est or refuting this claim, for a diagnosis of lympho medullary reticulosis (paragranuloma) is generally to infer a relatively favourable prognosis, a view will require revision if one in five is likely to into true Hodgkin's disease. This tendency f histological type of disease to change to another have detected also in the case of giant follicle lym the frequency of lymphosarcomatous degenerat this disorder is generally accepted, but these a have seen, out of 30 cases, 14 change to lymph 7 to Hodgkin's granuloma, 2 to Hodgkin's sarc 2 to reticulum-cell sarcoma. There is no p experience which accords with this.

The final third of the book is concerned with of the disorders allied to Hodgkin's disease, reticulum-cell sarcoma, lymphocytoma, lymphob and giant follicle lymphoma. These sections useful descriptions of diseases often neglected books, but they serve to underline the termi confusion: for instance, "lymphosarcoma" is to denote cases in which there is a single locally and destructive primary tumour.

The monograph is sumptuously produced, but its format nor its contents justify the price of 45

Treatment by Diet (5th ed. Philadelphia and J. B. Lippincott. 1948. Pp. 781. 60s.).—Prof C Barborka has found it necessary to rewrite, revise expand more than half of his book, and the result is a not only in appearance but in balance and common The foods, the menus, and the measures recom American in type, but they can easily be interpreted British form.

The World of Learning (London: Europa Pu 1948. Pp. 824. 60s.).—The second and "completely edition of a work first published in 1947, this large reference gives detailed information about educati tific, and cultural institutions throughout the world, with UNESCO and other international organisations, on to national institutions set out under their sp countries, arranged alphabetically. The informat printed that it is easy for the eye to pick it up.

Leaves from the Life of a Country Doctor (London: F. Muller. 1948. Pp. 195. 7s. 6d.).—This u tious and sincere little book of the late Dr. Clement really a series of notes and jottings of personal expe the course of a life devoted to the service of his fellow illness or in trouble; and the record shows how well he out his task. He seems to have possessed all the many butes needed by the country doctor, who can never tell emergency may next confront him. The book has been by Rutherford Crockett.

Manual of Public Health: Hygiene (3rd ed. Edin E. & S. Livingstone. 1948. Pp. 724. 35s.)—The edition of Currie and Mearns, designed specially for for the D.P.H. and degrees in hygiene, has been co revised. It differs materially from the older textb devoting most of its space to preventive medicine as by physicians, and only so much to communal sanit is required by medical officers of health; so the first is on inheritance and the second and third are on ma and child welfare and school hygiene. The chapt inheritance and vital statistics (biometrics) are cle really interesting, while those on infection and com diseases accord in the main with present knowledge theory, although there is no reference to the influ rubella on the embryo. The chapters on infection and tion accept "disease" as an element of parasitism, explains both our successes and failures in over endemic infectious diseases.

too much detail: it is doubtful, for example, whether the 4 pages illustrating technical apparatus for serum drying are worth their room in a book designed for practising surgeons. eye, the thirtees finally assessed, and treatment prescribed
ledge of the nbers of the team in consultation. If an
cornea on course of physical therapy is indicated, the
their atte is taken over by the medical officer in charge
mostly ysical medicine, who follows the case through his
fund partment, sending the patient back to the central
in clinic from time to time for review. Special courses
such as chrysotherapy or vaccine therapy, or general medical treatment, are arranged in the same way. From the appropriate specialist the patient receives the treatment prescribed by the arthritis team, and returns for review periodically. Those on chrysotherapy are seen weekly, and routine blood tests are made every three weeks, or more frequently if need be. Urine examinations are carried out weekly before each injection of gold or heavy metal. Patients requiring manipulation, splintage, or acidification of joints (Waugh) are seen by the surgeon and medical officer in charge of physical medicine together, and what may be termed a tactical plan of attack is drawn up.

By this method a period of one week usually elapses between the patient first being seen at the clinic, and the commencement of treatment.

Owing to the shortage of beds and nursing staff, fewer than 1% of the patients passing through the clinic are admitted to hospital; but our experience shows that however desirable it is to have inpatient accommodation, a great deal can be done for a very large proportion of patients attending only as out-patients. In the acute cases which need admission the same routine of preliminary investigation by the team, and planned treatment by the team, is strictly followed.

When the patient has passed through the clinic and received a course of treatment he or she is asked to return periodically for review. Attached to the clinic through the physical-medicine department there is a resettlement officer of the Ministry of Labour. Where a change of employment is indicated, or where return to the original occupation is impossible, the resettlement officer is consulted and an attempt is made to re-employ the patient, or to retrain him so that he can once more be a useful member of the community.

We hope later to publish the findings of this clinic, assessing the value of the various methods of investigation and treatment.

ation. Central abdominal pain associated with a ; of the occlusion type generally means spasm, pain—often milder—in the iliac fossa or at the neans occlusion. Dr. SWYER said that Newman ot been able to confirm Rubin's claim that the re waves in the kymogram derive from the tube, iss MOORE WHITE stated that after removal of t 1 in. of tube on one side, and all but $1^1/_2$ in. e other, she has still seen peristaltic waves in ymogram, which could hardly have originated tubes. Mr. SNAITH would not hesitate to do a 's test on account of transitory inflammation of ervix—except perhaps in the case of gonococcal itis. Dr. JACKSON and Miss MOORE WHITE men- that repeated patency tests must be done before ibes are regarded as occluded; and Dr. Jackson isised that use of the volsellum on the cervix may he tubes into spasm. The cervix should be handled .

Hysterosalpingography

s JOSEPHINE BARNES, F.R.C.S. (London), described osalpingography with water-soluble radio-opaque . Iodised oil, she said, is not absorbed from the or peritoneum; if it becomes inspissated in the it may conceivably cause stricture, while iodised-oil lomata have been known to form in the peritoneum. erg, in a monograph on *Hystero-salpingo-pelvi- ie*, describes the use of diodone injection ('Per- il') which, he claims, injected in dilute solution, es the pelvic organs and makes possible the osis of ovarian tumours and some other lesions. Barnes uses a watery solution of diodone. A viscous on has been tried but caused severe pain. The of viscosity is not a serious drawback, however, the watery solution does not cause spasm. An ntaneous radiogram is taken at the very moment the fluid is injected, and 20 minutes later another ken off the whole abdomen. The first shows the taken up rapidly into the tubes, and demonstrates lockage; the other shows excretion of dye already ining in the kidneys. The whole procedure is lete in about half an hour.

. ERNST FRIEDMANN (London) said that he had used cyazol' in nearly 50 cases without ill effects or plaint from patients. This preparation, which is diodone, will shortly be on the market in this itry.

Sims Test and Male Infertility

iss GERTRUDE DEARNLEY, F.R.C.O.G., reviewed briefly development of the subfertility clinic at the Royal Hospital, London. It was begun in her department Miss Moore White in 1937, and now carries seven tors and a part-time registrar.

r. MARY BARTON (London) said that she chose to the Sims test in the late follicular or ovulatory phase. ing mucus from the upper as well as the lower portion the cervical canal. The normal picture 24 hours r intercourse is of mucus densely invaded by spermat- a, many showing rapid movement. This picture out serious oligozoospermia and asthenozoospermia, not some other forms of male infecundity. The ical mucus allows only strong and well-differentiated matozoa to pass—apart from a few lively forms, microsperm. She noted that the head of the matozoon changes, when it enters the mucus, from ulate to olive-shape. A positive Sims test may k pyospermia, since polymorphs in the semen do penetrate the mucus; nor does the test reveal liative conditions of the testis. A couple may give ated positive Sims tests without conception taking e, even when no other recognisable infertility factors present, yet conception may occur after a focus sing pyospermia has been eliminated. For this and other reasons the Sims test should be supplemented by semen analysis. Spermatozoa may be found in the fornix in reasonable quantities when none are found in the cervical mucus; this does not imply male infecundity, however, since the mucus may be specially resistant to invasion. This finding should therefore always be followed by a cross-invasion test, the husband's semen being tested against the cervical mucus of another woman, and the wife's mucus against the sperm of another man. Sometimes the spermatozoa invade the test mucus, and conversely the wife's mucus may admit the strange spermatozoa. Such incompatibility is not necessarily permanent. In other cases, though the husband's spermatozoa invade the wife's mucus they quickly become immotile. Cervical mucus contains reducing substances which may be used to nourish the spermatozoa; and possibly the supply may be insufficient to meet the needs of a dense invasion. The Sims test may also reveal a curious condition in which no spermatozoa at all are found in the cervix or vagina, even though the semen obtained by masturbation is rich in them, and can be used successfully for artificial insemination.

Testicular Biopsies

Dr. FRIEDMANN discussed the technique of testicular biopsy. He takes the specimen with the patient under gas, and uses the type of instrument designed for liver biopsy. The specimens give valuable information about the state of the seminiferous tubules, and repeated biopsies can be used to check progress under treatment.

Testosterone Implants

Miss MOORE WHITE reported on the results of a series of testosterone implants made by Mr. George Qvist at the Royal Free Hospital. He implanted 200 mg. of testosterone, and in a few cases the semen showed improvement, but results on the whole were not encouraging. In one couple who did not report back the wife conceived and miscarried; no others conceived. Biopsies might have shown that some of these cases were unsuitable for implants, and in future it is hoped to do biopsies as a routine.

Vitamin E

Mr. NORMAN WARREN (London) had given vitamin E to 50 cases of oligospermia in doses of 30 mg. twice daily; semen analyses were done beforehand. There was an increase of density of spermatozoa in 23 cases, in 18 an improvement in motility and viability, and in 17 an increase in volume of semen of more than 0·5 ml.; and a lower percentage of abnormal forms was found in all cases where there was improvement in any of the other three factors. He concluded that this group showed some response to vitamin-E therapy.

Dr. H. A. DAVIDSON had treated 42 subfertile patients over twelve weeks with 'Ephynal' tablets, 10–14 mg. daily; 12 received methyl testosterone in addition. In 29 cases there were normal variations only; 6 showed some improvement, and 7 some deterioration. Two pregnancies were reported, one of which ended in abortion. Comparable results, he said, could have been found in a similar group receiving no treatment. Lest synthetic vitamin E is less effective than the natural product he proposes to treat a similar group on wheat-germ oil.

Dr. JACKSON had treated 50 subfertile men over periods ranging from three weeks to two years with 'Fertilol,' 'Viteolin,' or ephynal capsules in dosage roughly comparable to that of Dr. Davidson. Half of them received some other treatment as well. Some had large numbers of specimens examined and 35 had at least three such examinations; so it should have been possible to demonstrate any improvement. There was little evidence that vitamin E had any effect, good or bad, and most of the variations could be matched among men who had received no treatment. Of the wives,

INFERTILITY

FAMILY PLANNING ASSOCIATION'S CONFERENCE

A conference on infertility, arranged by the Family Planning Association, was held at Exeter on Sept. 25 and 26.

Congenital Absence of the Vas

Mr. DONALD H. YOUNG, F.R.C.S.E. (Liverpool), described cases of congenital absence of the vas deferens. In the first he had seen, the semen was found to contain no spermatozoa, though biopsy of the testicle showed that spermatogenesis was normal. At cystoscopy, the bladder and ureteric orifices appeared normal, but no ejaculatory ducts were visible; and at operation the vasa deferentia were found to be represented by thin fibrous cords. Fructose is normally present in semen, and is formed in the seminal vesicles; its absence implies disease of the vesicles or absence of the vas. Up to 1940 some 30 cases were noted in Germany among patients undergoing compulsory sterilisation under the Nazis; these amounted to 0·5% of the total number sterilised. A few cases have been reported in the United States since 1945. Cases of obstruction of the ejaculatory ducts give the same seminal findings but can be distinguished by the fact that the vas is palpable.

Similar cases were described by Dr. G. L. FOSS (Bristol), Dr. H. A. DAVIDSON (London), and Mr. LINTON SNAITH, F.R.C.S. (Newcastle); and by Dr. T. MANN, (Cambridge), who added that human semen contains, besides fructose, something under 1% of citric acid. This derives, in man, from the prostate, and might, he suggested, be used as a measure of prostatic secretion. Mrs. CLARE HARVEY, who has been doing fructose estimations in semen since last February, said that in five or six specimens showing azoospermia which she examined fructose was present, whereas the only specimens without fructose showed normal sperm counts. Dr. MANN pointed out that if an occlusion is above the seminal vesicles fructose will be present in the semen: *moreover human semen is not of a constant* chemical composition; it varies, in the same subject, from specimen to specimen.

Supravital Staining

Miss ANITA MANDL described a method of supravital staining with buffered soluble blue, by which living spermatozoa are stained pink, and dead ones bluish-purple. Motility, she said, is not necessarily a measure of viability. Mrs. HARVEY said she has used the method, with semen incubated at 37°C. Though all motility ceased after 24 hours it was 4–5 days before all the spermatozoa took on the blue stain, though the proportion of blue-staining spermatozoa increased steadily during the period of incubation. Dr. MANN pointed out that motionless spermatozoa are not necessarily dead, and may revert to motility; and Dr. G. I. M. SWYER (London) summed up the action of the stain as differentiating the irreversibly immotile spermatozoa from those which are motile and reversibly immotile.

Mr. A. WALTON, D.SC. (Cambridge), noted that the motility centre is in the middle-piece and tail; the head takes no part in it. Dr. SWYER said that the different parts of the spermatozoa take up the stain differently, the tail dying first and taking the blue stain while the head is still pink. "They die from the tail upwards."

Blood-supply of the Testis

Dr. R. G. HARRISON (Oxford) described the blood-supply to the testis in various animals, and showed a number of beautiful X-ray photographs of animal testicular vessels injected with colloidal bismuth. In most of those examined the testicular artery was a single vessel which formed a number of convolutions before reaching the testis. The wallaby, man, pilot whale offer exceptions to this usual arra In the wallaby the artery, instead of convoluting, into a sheaf of small vessels which later unite vessel supplying the testis; and the veins pampiniform plexus which collects up into four In the pilot whale there are no convolutions splitting—the artery plunging straight into the before it breaks up. In man the artery runs straight, giving off branches to the cord and epi and then divides into two branches, one to the and one to the posterior border, which ramify o surface of the testis, sending in, towards the medi branches which loop back on themselves. It d as the textbooks say, run directly into the medi and this is important since in the treatment of c chidism one of the main branches may get ca There is some relation between arterial coiling fall in temperature between abdomen and test the ram the veins surround the artery, sugg arrangement for the exchange of heat. A rise perature affects fertility: when the testicles are to the abdomen in animals they become ste the continuous application of heat to the t injurious to fertility. Short hot baths are harmless, but evidence is needed about the e repeated hot baths, of warm underclothing, and occupations as stoking.

Mr. YOUNG asked whether varicocele, which to be associated with subfertility, raises the t temperature; and other speakers discussed the of elastic suspensory belts often worn by *especially footballers.* Dr. MARGARET HADLEY J (Exeter) remarked on the large number of fo among husbands of women attending the Exet fertility clinic; and Dr. R. G. CROSS (Dublin) that the British are supposed to be sterilising the by hot-bathing, and the Americans by wearing tight pants. It is time, he said, that we pa attention to the kilted races.

Mr. SNAITH said that there is no evide correlation between varicocele and subfertili patients believe that there is, and they need re Dr. WALTON mentioned that the largest varicoce ever seen was in a very fertile ram. Dr. W. J. noted that the chemical output of the gonads is by temperature: if they are transplanted to *the output of hormones is increased.*

Uterotubal Insufflations

A paper by Mr. ALBERT SHARMAN, M.R.C.O.G. (was read in his absence by Miss M. MOORE F.R.C.S. (London). He reminded the meeting importance of using carbon dioxide rather tha *oxygen for the Rubin insufflation test,* and s he has not encountered any ill effects from using a of 250 mm. Hg as a routine. Tubal spasm is a cause of negative findings, and he has found t 32% of cases showing non-patency in a single t occluded tubes. If, after a negative result, th is dilated and a second insufflation is done, th may be resolved. Insufflation, or even dilatatio may be followed by *pregnancy, and this* i attributed by Rubin to the establishment of removal of the cervical mucous plug, or dilatatio tubes, or possibly to a psychic effect. Mr. S believes that the addition of a kymograph insufflation apparatus makes it possible to di between tubes which are normally patent an which are the site of spasm, stenosis, or adhesion the tube.

Dr. JACKSON said that it is often possible to tiate spasm from stenosis by the type of pain not to the radiographic appearance of silicosis the degree of emphysema present.

V. C. DREESSEN (U.S.A.) surveyed the develop- nd trends of studies of pneumoconiosis in the States during the past decade. Physiological h and clinical investigations have opened up many lds; but further basic studies are needed, since it ming apparent that other air-borne particulate ls besides silica and asbestos are causing serious ary disease.

eat paper by Dr. A. J. VORWALD (U.S.A.) on aceous earth pneumoconiosis was memorable if ecause it showed how an investigation should be

maceous earth is a fine-grained material composed siliceous residue of diatoms and other microscopic that live in water. Clinical and experimental evidence at both crude and fluxed calcined diatomaceous earth able of producing pulmonary fibrosis, the latter more he former. Though there are scattered foci of sation and necrosis, not unlike the pulmonary response ded quartz, the fibrosis is more diffuse and cellular in d involves more especially the alveolar walls in addition periarterial and peribronchial tissue. The alveolar are either obliterated, greatly distorted and small, or d to form emphysematous areas. The diffuse cellular ary fibrosis is more serious than the discrete nodular of uncomplicated silicosis, and is perhaps responsible pronounced shortness of breath seen in this disease. sed calcined product, which contains more cristobalite of free silica) than the crude material, has a deleterious n any associated tuberculous infection. Dr. Vorwald that he has not yet finally identified the specific nent of diatomaceous earth responsible for the observed l and experimental effects.

A. BRUUSGAARD and Dr. K. B. SKJELBRED- SEN (Norway) described cases of silicatosis in a mill, and Dr. F. BARTÁK and Dr. M. TOMEČKA hoslovakia) showed that a pneumoconiosis, which called stannosis, can develop after inhalation of the of tin oxide. They did not, however, make it very whether they regard the dust of tin oxide as noxious ert, though they did point out its radio-opaque ties. They also drew attention to the "euphoric of those even gravely affected"—presumably those ing conspicuous X-ray changes—and mentioned acrophagic but no other type of reaction in the lung e. (All of which suggests that the dust of tin oxide t very harmful and that "stannosis" can be classed e of the benign pneumoconioses, of which siderosis e best-known example.)

e physiological aspects were discussed by, among rs, Dr. TORSTEN BRUCE (Sweden) who dealt with cise-tolerance tests and spirometry. He stressed fact that the dyspnœa of silicosis has a physiological ground and that the lungs have several mechanisms reby they can adapt themselves to the strain pro- d by the destruction of air cells. In addition to nical stimuli he mentioned the significance of the ous regulation of both ordinary and the forced thing in silicosis. Dr. P. PELNAR (Czechoslovakia) ribed a new method of examining respiratory and ulatory functions with special reference to silicosis. method consists in continuous measuring of the gen and carbon-dioxide equivalents at rest, during cise, and during recovery from exercise. In silicosis finds that his results do not correlate well with X-ray findings, but there is a correlation with the e of dyspnœa and the degree of incapacity.

Science reporting and interpretation does not accomplish urpose . . . if it does not bring about an appreciation and ilization of the method of science in everyday life. . . . e great mass of the people, through accurate and interest- accounts of the successes and failures of science, can pse and understand that essence of science, its trying, ng, and trying again, if they build their own convictions this is a good, sensible, successful, and useful method, there is hope that they will apply it more widely to yday life, to our human relations, to running our busi- es, to our governments, to everything that we do."— rson DAVIS, *Science*, Sept. 3, 1948, p. 241.

THE NEW ZEALAND HEALTH SERVICE

FROM OUR CORRESPONDENT

THE report of the Medical Services Committee has been tabled in the House, and discussed in the press, but not so far by profession or parliament. The committee was composed of four members from the British Medical Association, and three (two medical) from the health department, with a legal chairman. Its object was to advise the government about the present medical scheme, which has been seven years in operation, and to suggest ways and means of overcoming admitted abuses. It thus represents the first major effort to overhaul the system; but it does not deal with many large aspects such as hospital reform, nursing, medical education, and the health department.

Administration.—Committees for continuous advice in policy, discipline, and ethics are proposed for the first time, the onus to be placed largely on the medical men.

General-practitioner Services.—The present fee-for-service scheme is to be retained, a number of minor adjustments and simplifications being recommended. The report debates capitation, salaries, and combinations of these, but for various reasons finds them unacceptable.

Specialist Services.—These represent the only major gap remaining in the New Zealand scheme. The report proposes a fee-for-service system, an extension of "open" (part-time) hospital appointments to help to attain the greater number of specialists alleged to be required, and the construction of a roll of acknowledged specialists based on higher qualifications, experience, &c. Many details are left for negotiation.

Pharmaceutical Benefits.—Reasons for soaring costs are examined, and the imposition of a partial payment on the patient is proposed.

It will be interesting to observe the reception given to these proposals by parliament and profession, and what, if anything, will be done. The difficulty of such piecemeal repair work is obvious to anyone who takes a broad view of the whole system of health services. There never has been any attempt to synthesise and coördinate plans for the whole; and until this is done, essentially to the satisfaction of the parties concerned, there is little prospect of progress.

MEDICAL DEFENCE UNION

AT the annual general meeting, held in London on Tuesday, Mr. St. J. D. Buxton, the president, recalled that last December the union decided to admit dental practitioners to membership and to provide advice, indemnification, and protection for practitioners overseas. He warned members to consult the secretary as soon as they find themselves in any medicolegal difficulty, for successful defence is often prejudiced by action taken before seeking advice. During the year, he said, the union had conducted nearly 1600 cases, a rise of 14% on 1946. Previously the highest annual figure for indemnity and law expenses was about £21,000; but "this year we have already committed ourselves to a sum in excess of £40,000 and there remain more cases to be settled or fought in the courts." Of the annual subscription, still at £1, over 13*s*. went in law charges and indemnity claims.

The annual report shows that, with 32,075 members on July 20, 1948, the deficit was £1344 on last year's working. One case cost it £15,791, the member having paid £10 in subscriptions. The total funds available, inclusive of the guarantee fund, amount to £189,736.

Referring to the 49 cases of alleged negligence dealt with, the report discusses the trend of judicial opinion and says that it is becoming easier for claimants to succeed in any class of action arising out of insurable risks—e.g., traffic and workmen's compensation cases. "Therefore, the tipping of the scales in favour of plaintiffs in cases in which the union is involved is only part of a larger whole." Though the doctrine of *res ipsa loquitur* has not yet been wholly applied to a case involving medical negligence, some recent cases have come close to casting on the defendant the burden of proof that negligence was absent. Certainly, the courts have felt justified in accepting as proof of negligence evidence which would not have satisfied them before the war. Probably (the report suggests) this leniency is only temporary, and judges may presently recognise that the pendulum has swung too far.

14 (28%) conceived, which does not compare favourably with 33% of conceptions among 324 wives attending the clinic during the same two years. She concluded that though there is little evidence that spermatogenesis can be improved by vitamin E, it is possible this vitamin may prevent further degeneration in an already damaged testis.

Basal Temperature Charts

Dr. JACKSON said that the morning rectal temperature chart helps the doctor to sort out irregular cycles, to prognosticate the day of menstruation, and to diagnose pregnancy, sometimes in advance of a report on the Aschheim-Zondek test. Persistence of the high "luteal" temperature beyond fourteen days strongly suggests pregnancy. In 2 cases she has been misled: both patients were obsessionally anxious for a child and induced a state of phantom pregnancy. Their periods were inhibited for some months; their rectal temperatures were raised, and they insisted on remaining in bed for weeks. The temperature did not fall until they were made to get up and go about their business. Such cases, however, are rare.

Impotence and Fertility

In the general discussion on the foregoing group of papers, Dr. DOROTHY TAYLOR asked for advice on the treatment of partial impotence. Miss MOORE WHITE said that successful artificial insemination of the wife with the husband's semen often resulted in the husband's recovery from impotence. Dr. DAVIDSON mentioned a syringe which he and Dr. Joan Malleson had devised for taking up the semen from nocturnal emissions, for the artificial insemination of the wife; the number of emissions can be increased by giving testosterone. Dr. JACKSON had found one husband who recovered on being directed to do so by the doctor, while Dr. JOHN HOLT (Holland) finds a successful method is to forbid the husband to have intercourse with his wife.

Dr. A. C. CROOKE (Cambridge) said that one group of steroids, which includes testosterone, is androgenic, while another group is spermatogenic. He has had promising results in 3 out of 4 cases treated with androstenediol dipropionate, which he synthesises himself.

Miscarriage Related to Seminal Characteristics

Mrs. HARVEY discussed the relation of seminal characteristics, especially oligospermia and high numbers of abnormal spermatozoa, to abnormal development of the fœtus resulting in miscarriage or stillbirth. Her figures refer to a group of over 700 husbands attending the Exeter subfertility clinic who were responsible for 745 conceptions ending as follows: 409 live births with 15 neonatal deaths, 261 spontaneous miscarriages, 24 stillbirths, 5 ectopic pregnancies, 2 induced abortions, 27 pregnancies still in progress, and 17 doubtful early conceptions. Moreover, 371 wives have had no known conceptions. She showed that the number of spermatozoa, and their motility and morphology, but not their viability, are correlated with the chance of conception. There is little evidence that any single factor in semen conduces to miscarriage or stillbirth; but the miscarriage-rate, contrary to expectation, is highest among the wives of men in the 3A group [1]; which implies that the maximum chance of miscarriage is associated with a density of 40–59 million sperm per ml., and falls off on either side of this range.

Assessment of Infertility Data

Dr. SWYER gave a survey of papers on infertility published in four American and two British journals in 1946–47 to show how exceedingly inaccurate, and even unscrupulous, authors sometimes are in the presentation of their papers. In the subsequent discussion editors were criticised for publishing such misleading work.

PNEUMOCONIOSIS

SOME FURTHER COMMUNICATIONS

AT the International Congress on Industrial which we reported briefly last week, four whole were devoted to pneumoconiosis, and these separate notice.

A paper by Dr. J. DANTIN-GALLEGO (Spain), New Ideas on the Ætiology and Pathogenesis of. was based on the premise that until recent times has not been studied scientifically and that nc yet considered the effect of the environment development of the disease. He thinks that too attention has been paid to the chemical effect of and that the radiographic appearances have correlated with the pathological anatomy. For part he assigns great importance to the constitution and physical properties of inh particles on the one hand and the human the other.

Prof. JETHRO GOUGH and Dr. J. E. W presented a new technique for cutting thin the whole lung and mounting them on paper, which constitutes a distinct advance in the lung lesions. The focal emphysema of coal trimmers is shown with great clarity, and the logical features can be correlated with the rad appearances.

Dr. A. BRUUSGAARD (Norway) described some of pneumoconiosis in workers exposed to silicon dust, which has been thought to have little effect lung tissues. Of 32 workers in a carborundum 10 showed radiographic lung changes, some of nodular in character. In the more advanced was slight disability. Most of the affected worked in a dusty atmosphere for more than fift (In the absence of pathological evidence it is not to be certain about the cause of the X-ray some might be due to deposits of carbon fibrous changes might account for the incapac in some cases.)

Pneumoconiosis in coalminers was the subj number of papers. Prof. E. J. KING with HARRISON and Dr. S. C. RAY dealt with the aspect, while Dr. I. DAVIES and Dr. K. J. MA a classification of coalminers' pneumoconiosis X-ray appearances. In the South Wales area X-ray abnormality consists of minute c 1·5 mm. in diameter, circular in outline and density. These may remain discrete or ag form larger granular opacities. Two stages of coniosis, simple and complicated, are recognised. stage is subdivided into categories, three in the type and four in the complicated.

Progression of the X-ray shadows in c described by Dr. C. M. FLETCHER. Two groups studied: in one the men had had no further coal dust after the first radiograph, and in the they had continued to work in the mines. In the no increase in the characteristic generalised of simple pneumoconiosis was seen, whereas in the the opacities increased in number rather than In both groups, however, a majority had de localised coalescent or massive shadows associated a raised erythrocyte-sedimentation rate at the examination. It is concluded that this type of pro is not dependent on continued exposure to coal du to an additional factor which may be infectio tuberculosis.

Prof. J. LECLERCQ, with Dr. E. BAIG Dr. BONTÉ, and Dr. G. DECLERCQ (France) demo the value of tomography in localising the masses pseudotumoral form of silicosis, and Dr. G. C. E. (Netherlands) discussed the efficiency of mass min radiography in the detection of reticulation and tion. A practical trial with patients suffering fro earliest stages of granulation proved that, when with large films, the 40 mm. miniature films re the changes well. Studies of the electrocardiogr silicosis by Dr. F. LAVENNE (France) showed the most important changes were those usually asso with right ventricular hypertrophy and that they

Letters to the Editor

ENTAL INTRA-ARTERIAL INJECTION OF DRUGS

—May I make some comments on Mr. Sol. Cohen's of Sept. 4 and 11 ? begins with the assumption that the phenomena scribes are due to intra-arterial injections, which vascular damage and thromboses, but he does not that all the injections actually occurred by this In a high proportion of cases no evidence of rterial injection could be found at operation. ct that arterial thromboses developed in some of is no proof that the drug was injected into an . Indeed, there is much evidence that Mr. Cohen's ptions are unjustified :

ccording to several authors he quotes, thiopentone en injected into arteries without pain or other ill effects.

ith thiopentone the symptoms began with local or peri- pain immediately on beginning the injection ; but bi take time to form.

n some of the cases there were no changes in blood- re, and no clinical signs of arterial or venous obstruction, t operation thromboses were not found in the blood- s (e.g., case 7). In fact, the radial pulse may be full, case 3. The same is true of the case of gangrene ing 'Myanesin' injection which he mentions.

n his own showing, the initial symptoms in the thio- ne mishaps are completely relieved by sympathetic block, which indicates that they cannot be due to sible pathological changes in the blood-vessels, such as boses.

n the thiopentone cases, the pain which comes on iately after injection may be followed by vasodilatation e side, or in the whole of the hand and forearm, or by te hand and cyanosed fingers. These are the signs of ve arteriolar vasoconstriction. The vascular and other es were relieved by sympathetic block, indicating that originated in changes in the activity of vasomotor nerves. patient later developed Raynaud's phenomena, which result from purely neurological lesions, such as gomyelia. Two patients developed severe generalised otor reactions and poor pulse in the opposite limb. e are the effects of alterations in the activity in motor nerves.

In the affected limb, in addition to the pain, there later ar muscle spasm and sensory disturbances, such as ng, a sensation like a tight band round the limb or that rm is being broken, vascular changes, œdema, blisters, punctured sloughing sores. In case 1 the hand and rm were completely anæsthetic and the hand tingled. se 3 the entire hand and ulnar aspect of the forearm were sthetic, and extension, pronation, and supination move- ts were impossible. In case 5 there was complete loss oluntary movement of the wrists and fingers, but passive ements were possible and painless: case 8 showed ove " anæsthesia. In cases 4 and 8 anæsthesia and phy of the intrinsic muscles of the hand appeared, and two cases carpopedal spasm. All these symptoms are iliar to neurologists and are identical with those resulting n irritation of peripheral nerves—e.g., in brachial neuritis causalgia—and with the initial effects of injection of octocaine ' into a nerve.

n Schmuttermayer's case quinine was injected into the er arm producing the signs of a radial nerve palsy ; but Cohen states that this also caused symptoms suggestive ntra-arterial injections.

ll these facts suggest that the author is confounding effects of intraneural and intra-arterial injection. t the effect of thiopentone is primarily on the nerve s and fibres is also shown by its very use as an sthetic and by the following case under my care :

miner, aged 42, had a thiopentone injection into left arm for a hernia operation. During the injection had some pain in the upper arm and shoulder, and r this he developed pains in the whole limb, with e tingling, and the signs of a brachial neuritis, lting in marked weakness and wasting of the deltoid, ati, rhomboids, and upper-arm muscles, winging of the scapula, and weakness of the trapezius muscle causing the shoulder to drop on this side. A glove anæsthesia was present, but the pulse-pressure and blood-pressure were normal and equal on the two sides of the body and the symptoms gradually improved. It is difficult to explain such a case as due to arterial damage.

As Mr. Cohen says, intra-arterial injections are often painless unless the artery is covered with a network of sensory nerves. This suggests that sudden severe local pain following injection of drugs is due to their injection into the sensory nerves around the vessels or into the main nerve trunks. (The former probably occurred in case 1, in which blood was found around and in the adventitia of an artery.) Injections into nerves may produce marked peripheral vasodilatation, through liberation in the blood-vessels of acetylcholine from the vasodilator fibres in the nerves. Acetylcholine has been shown to accelerate blood-clotting, and excessive vasodilator nerve impulses may therefore eventually precipitate thromboses. It is unnecessary to imagine that thromboses in the arteries supplying the nerves of the limb are responsible for the neurological symptoms. It is much more reasonable to suppose that the arterial thromboses follow the neurological lesion.

The arterial thromboses which later occurred in some of the cases Mr. Cohen describes were no doubt important in causing the onset of gangrene. Nevertheless gangrene may occur as a trophic lesion, resulting from damage to nerve-fibres (as in tabes, leprosy, and bed-sores), without vascular lesions being present.

London, W.1. R. WYBURN-MASON.

DIETARY FAT

SIR,—Your leading article of Sept. 18 gives a fair account of our present knowledge of dietary fat. You will perhaps allow me to comment on it and on Dr. Walker's letter on p. 476 of the same issue.

Most of us will agree with Dr. Walker that it is unwarranted to define the deficiency symptoms of a nutrient, the minimum requirement of which is not yet known. However, the comparisons of our rations with the fat intake of other countries are not accurately quoted. Thus he states, on the authority of Fleisch,[1] that the daily fat intake in Switzerland during the war period was 40–50 g. A glance at the curves on p. 891 of Fleisch's paper shows that these figures held good only for the period from the end of the first quarter of 1944 until the end of the second quarter of 1945. Six months later the fat consumption went up by 50–60%. Even this summer, 3 years later, visitors could see that the Swiss public was still as eager a consumer of butter and whipped cream as the holidaymaker from Britain. It is perhaps fair to add that food rationing was introduced in Switzerland in 1942 and that light, moderate, and heavy workers obtained 600, 1200, and 1800 extra calories daily, consisting mainly of meat, cheese, and fats.

Your leading article enumerates the probable reasons underlying a craving for fat. Experience indicates that fat consumption depends more on living standards and national food habits than on geography, climate, or race. The average daily fat consumption in England rose from 99 g. per head in 1909–13 to 124 g. in 1934.[2] Similar rises occurred in other western industrial countries and also in the United States; and the fitness of the South African Bantu or of the Japanese, with a daily fat intake of 30 g. or less, will be of little help in establishing our minimum requirement.

In dealing with this problem the importance of the non-caloric functions of dietary fat have not always been sufficiently recognised. In a properly balanced diet[3] not only is the absorption of fat-soluble vitamins and of calcium and phosphorus dependent on adequate fat intake, but the fat also exerts a sparing action on many of the B vitamins. Another important relation of dietary fat to the economy of food utilisation was recently demonstrated in animals.[4] A mixed diet containing an adequate amount of fat secured extra calories for work, growth, and

In England Now

A Running Commentary by Peripatetic Correspondents

A FRIGHTENED young man of six met me in the duty room that night. I was told he had swallowed some berries, so for once having thoroughly read my journals, I seized a tube and washed him out. That sounds easy, but I have had difficulty in penning this, for my index finger has still not recovered from the bite he gave me. By now he had fixed dilated pupils. *Atropa belladonna, thought I, until I saw green berries.* I called a colleague. Of course, when he got there the boy's eyes were normal, his adrenalous fear having passed.

By this time the boy had recovered from his treatment, and (I feel with malice) stated that his playmate had eaten more than he had. But we were loth to wash out more stomachs until we knew what the berries were. So two porters and I, very shady-looking characters all, trailed the boy's parents through hosts of doctors, all of the same name and all very sleepy, and finally got a description of the berry-bearing area. Armed with a torch, and keeping a wary lookout for the copper on his beat, I scaled the fence of the park, and crept like a felon through scrub and semi-desert until I found a good strong growth of berried weed in the place described. Tearing off a large portion of bush, I returned to the hospital. There, with the aid of the *Lancet* for Sept. 11 and one forlorn berry on a large mass of vegetation, we identified *Solanum dulcamara*, or Woody Nightshade.

While the radio blared "Woody Woodpecker," we waited for the boy's pal, a wee thing of 4, to get to the hospital. As soon as she arrived I again passed the tube. It blocked. So my colleague, asking her to open her mouth, tickled her tonsils with a spoon. She vomited. He told her it was not enough. So she obligingly vomited again. He then said "Open wide," and made her sick again. A much better method, thought I, massaging my finger.

My colleague now rang up a toxicologist of repute to ask him for an antidote. "An antidote?" quoth he. "What a question to ask me. I only know what killed *'em, not why they got better." A pleasant outlook . . .*

As the nursing staff had only kept the non-berry-bearing residue, I finished the evening's entertainment by sorting through the whole dirty linen of the ward for *twelve hours (3 incontinents!), to find at last a berry* from the boy's stomach. If this proves anything, it is my pet theory that children love to be made sick. What else can swings, roundabouts, and synthetic sweets do to make them *feel and look so happy?*

Please, dear *Lancet*, continue to publish accounts of rarities just a week before I need them.

* * *

In the present emergency, a number of practitioners have approached me for notes on the plastic surgery of the cigarette, and these I now give (I'm sure the Medical Research Council won't mind).

Dislocation, due to sale without the usual container, is readily reduced by running through the fingers several times.

Fracture is invariably compound, and occasionally comminuted. Neither plaster nor Unna's paste should be used as occlusive dressings. Collodion is all right if you don't mind the smell of shoeing horses. The treatment of election is recapsulation by the method described under plastic reconstruction (below).

Herniation of the contents at both ends is incurable, though in early cases I always put it back with an eye spud.

Plastic reconstruction by the Wandsworth-Dartmoor technique is rapidly gaining popularity *even in Harley Street*; the opportunities for it, in general practice, can be supplemented by putting out more ashtrays in the waiting-room and looking underneath the grate in the rooms to which patients have access. *Messrs. Fiddle and Flog of New Ravenish St.* will shortly advertise a portable steriliser for the squeamish, and the operation should then become a routine procedure throughout the profession. In its simplest form, it is undertaken by *selecting* a suitable former, of a diameter slightly greater than that of your own or your patient's favourite brand. Old metal catheters matched to the size of a Weight, a Player, and a Churchman's No. 1 make a suitable *armamentarium*, or a convenient set may be turned up from aluminium rod. A suitable c rolled on this, the length of the implants is carefully to provide a clean surface at each end, and the f withdrawn in stages, being replaced by the implants, are slightly reduced in diameter by rolling between and thumb. This operation may with practice be c in the privacy of the pocket. A single strand of fine wire passed longitudinally *down the middle* of the article protects the operator's clothes from any po hazard during consumption.

Exsanguination-transfusion, with dilution of the *rarely meets with success, practical* or social. Some who must have impaired powers of olfaction, reco a diluent:

℞ Tussilag. fol. exsicc.
Rubi fol.
Lavand. flor.
Trifolii flor. aa part. aeq.
M. Trit. secundum artem.

I don't use any of these techniques myself. I saved all fifteen of my tobacconist's kids from of external auditory meatitis—I should worry.

LETTER TO A NEPHEW

—I was a little perturbed by the views of the ctionate uncle" in your Students' Number. I t understand why the vocational urge to be a good r should be regarded as unhealthy, or why high should be incompatible with being a "wise, y, reliable human being."

e two attributes are surely independent of each . True, many idealists are extremely bigoted and w-minded; but there are others, of whom the William Temple may be taken as an example, who he most human of men. I am sure that if the ctionate uncle" were to delve into his experience ould find far more neurotics and other unstable nalities among those with low ideals than those with

is condemnation of idealists as freaks is deplorable. re would the drive for achievement in any walk of e found if it were not for ideals? The world would through sloth and idleness to its own destruction faster than it is drifting now. The man of ideals t the very person of integrity to whom the distressed d turn in time of trouble. Although the idealist es his wagon to a star, the wheels of his wagon are the less firmly placed upon the ground, and the that he has acquired in guiding them through the journey of life makes his advice all the more ble in helping those who are not so successful. ism and realism are complementary.

would suggest that the delightful picture that the ctionate uncle" drew of the trusted family doctor demands a definite vocation. He sets an ideal in cal practice that requires from the doctor unremit- service to his patients at all times of the day and . I believe that most men are idealists. They oth to admit it, however, because of the unfor- te association in men's minds of idealism with w-minded fanaticism.

X.Y.Z.

PRIVATE PATIENTS NOT ADMITTED

SIR,—In your last issue you take exception to my letter to the *Times* of Sept. 15 in which I uphold the decision of the Minister of Health to exclude private patients from the new health centres because, in my opinion, this is bound to lead to either preferential, more considerate, or better treatment for them. You say—

> "The truth seems to be that the great majority of patients remaining as private patients do so in order that they may suit their own convenience as to when, where, and how often, they consult their doctor."

But surely if private patients coming to the health centre are permitted to "suit their convenience" as to when they see their doctor, whereas other patients, except emergencies, have to make appointments between certain hours, they are receiving preferential treatment, and here of course I am using the term treatment to imply service and not medical treatment for disease.

It is quite permissible to argue that to admit private patients to health centres might have compensating advantages to the doctor or even to the service as a whole by saving the doctor's time, but to deny that it would involve two standards is absurd.

London, S.W.1. SOMERVILLE HASTINGS.

SELECTION OF TEACHERS

SIR,—Your Students' Number (Aug. 28) contained a concerted attack on the problem of selecting medical students. A scarcely less important problem is the selection of clinical teachers. The present system is very inefficient—so many teachers are dull and incompetent, so few brilliant and inspiring. Your peripatetic correspondent's son (Sept. 11) might be quoted.

I do not know how teachers are selected, but it seems that teaching ability is rarely considered. For those who have to make the choice it is indeed very difficult to assess; yet they never take the obvious step and ask students. Only his audience can judge whether a teacher is lucid and capable of holding its interest. Surely, Sir, there is some way of fairly estimating a man's ability to teach by asking those whom he has taught? This should apply as much to the promotion of a registrar to a chief assistant's post as to the appointment of an honorary at a teaching hospital. It is true that there are not enough good teachers to go round, but part of the reason is that many potentially good ones stop teaching when they have finished as registrars. If medical school authorities could judge which of the registrars were able teachers, they could encourage them to continue to teach. Provided their clinical and scientific ability was sufficient, an improvement in the general standard of teaching should result. CLINICAL STUDENT.

THE CASSEL HOSPITAL

SIR,—May I make two corrections to your account last week of the procedure used in selecting nurses for the Cassel Hospital for Functional Nervous Disorders?

Your heading described "The Cassel" as a mental hospital; it is a hospital for neurosis and it has never been a mental hospital nor admitted psychotic patients. The point is important in so far as your note may affect our recruitment of State-registered nurses for the year's course and certificate in the nursing of neurosis, or may discourage applicants for the Cassel bursaries, which permit a general trained nurse to obtain three months' intensive experience in this work, and then to return to her own hospital.

Secondly, Dr. C. H. Rogerson, my predecessor, is innocent of responsibility for the procedure, which owes much to War Office Selection Board methods. The system was introduced by the Matron, Miss D. Weddell, with the technical assistance of myself and my colleagues.

T. F. MAIN
The Cassel Hospital, Ham Common, Medical Director.
Richmond, Surrey.

". . . The great epidemic diseases are seven in number, malaria, plague, cholera, smallpox, typhus, yellow fever, and influenza. Others have had episodes of widespread activity, but these seven have been the great killers. . . ."—Dr. F. M. BURNET, F.R.S., *Med. J. Aust.* Sept. 11, 1948, p. 283.

storage. These extra calories were not available after omission of fat from the diet although an isocaloric mixture of carbohydrates and proteins was substituted. Lack of more detailed knowledge led Burr[5] to conclude: "There are ample reasons for recommending that the fat intake be not reduced much below the normal established habits."

London, W.1. Z. A. LEITNER.

SUPERNUMERARY NIPPLES

SIR,—While performing routine release medical examinations in the R.A.F. in 1946, I noted the incidence of supernumerary nipples in all cases. I also noted, by questioning and examination of the medical records, the cases of neurotic illness. I can thus present figures, tabulated below, of both a "neurotic" and a "non-neurotic" series examined under identical conditions. I had no idea of finding a connexion between supernumerary nipples and neurosis as the two factors were observed for different ends. The two series are selected only in that all subjects had passed a medical board on entry and had not been discharged on medical grounds —i.e., those severely handicapped by neurosis do not appear. I found no supernumerary nipples among 139 W.A.A.F. personnel, but the whole milk-line was not examined in their case.

—	—	No. of men	No. and per cent. with accessory nipple
Men without obvious neurotic illness	—	643	48 (7·5%)
Men with neurotic illness at some time during their service	Downgraded on this account	24	2 (8%)
	Not downgraded on this account	40	3 (7·5%)
	Total	64	5 (8%)

My figures do not show any significant difference in the incidence of accessory nipples between the neurotic and non-neurotic members of this group.

London, W.2. GORDON HESLING.

POLYARTERITIS NODOSA

SIR,—In connexion with the statement by Dr. Tonkin and Professor Pulvertaft (Aug. 21) that more than half of the cases of polyarteritis nodosa survive for a considerable time, the following report may be of interest.

A married man, aged 36, was admitted to St. Charles' Hospital on April 12, 1946, with loss of weight, persistent pyrexia, asthenia, pain in joints, cough, and occasional small hæmoptyses. He had been subject to "rheumatic" pains, but had had no serious illnesses. Three years previously he was in another hospital on account of hæmoptysis, pyrexia, night sweats, and a "red eruption" on the legs; blood-count normal and blood-culture negative; provisional diagnosis was meningococcal septicæmia. From 1943 till April, 1946, his health was fairly satisfactory except for occasional severe attacks of pain in the joints, legs, and arms, unrelieved even by complete rest.

On admission.—Thin, pale, and wasted. Temperature 99·2° F; pulse-rate 96 per min.; blood-pressure 190/70 mm. Hg. Urine: no albumin. He complained of blood-stained sputum, and pain in knees and lower back. Cardiovascular, respiratory, digestive, and central nervous systems clinically normal. Skin normal except for a few purpuric spots on the legs.

Investigations.—X-ray examination: evidence of bronchitis at base of right lung; lumbar spine normal. Sputum: no tubercle bacilli on examination. Blood-cultures negative. Urine: microscopical examination showed an occasional leucocyte. Blood Wassermann and Kahn reactions negative. Blood proteins normal. The only positive findings were: (1) constant moderate polymorphonuclear leucocytosis, with no eosinophilia; and (2) increased blood-sedimentation rate.

Progress.—After two weeks the temperature settled to normal, but the patient still looked ill and had joint pains. The diagnosis was obscure until the discovery of small hard nodules in different parts of the body on May 1. The nodules were dermo-hypodermic and mostly on forearms and thighs. A tentative diagnosis of periarteritis nodosa was confirmed later by histological examination of an nodule, the report on which read: "Periarteritis Chronic inflammation around and in the walls of vessels, with in places numerous polymorphs, and one contains a thrombus."

Unsuccessful attempts were made to demonstrate and/or infective ætiological factors. However, the atology suggested a chronic low-grade infection, patient was given empirically a course of parenteral from May 14 to 30. While this was being admini temperature rose each day to 99–102° F, although it normal in the two previous weeks.

The patient's general well-being improved rei and on May 24 only one small nodule on the inner of the right forearm could be seen. He was di home on June 10, and afterwards resumed his occupation of club steward. I heard recently t still well.

St. Charles' Hospital, London. A. I. SUCHETT-

POLYTHENE TUBING IN BLOOD-TRANSF

SIR,—Having read the article by Dr. Farq Dr. Lewis in your issue of Aug. 14, I conclud polythene catheters would be useful in blood-tr particularly for patients requiring fairly large of whole blood or packed red cells at a very Using a needle as an introducer, I have found it to insert polythene catheters, of 1 mm. bore, into The method is as follows:

A suitable length (about 9 in.) of polythene tubing, outside diameter of approximately 1·5 mm., is used will pass through a standard blood-taking needle (diameter approximately 1·75 mm.). The end of the is bevelled to coincide with the bevel of the needle. a side opening was also made in the catheter, but found that this weakened it so much as to make it to introduce. The catheter is inserted into the ta until the bevels of needle and catheter almost Under local anæsthesia, the needle, with contained is then inserted into the vein. The catheter is now through the needle for about 6 in. and the needle is w Where possible, the needle has been introduced into of the upper forearm and the catheter has been upwards until it is an inch or two beyond the el

If a tourniquet is used to produce venous dist should be released as soon as the needle has been Failure to do this may result in a leak at the si puncture when the needle is withdrawn. To ex blood is allowed to run down the catheter, which attached to the standard drip apparatus by me suitable cannula. This can be prepared by cutting needle so as to leave the shaft, approximately 1 with a smooth tapered tip. In all cases this has been to give a firm joint that does not leak. Suitable must be selected individually, for there appears to siderable variation in the outside diameter of the A sterile gauze dressing is applied at the site of p and the whole is held in position with a length of 2 in. st completely encircling the arm. The tubing of the is strapped to the arm in the form of a loop so as to direct traction on the catheter, but the cannula con should be left exposed so that any leak may be easily det The rate of flow can be easily regulated between 120 drops per minute, while greater rates may be by using positive pressure.

With this method whole-blood and packed-cell fusions have been easily maintained at a rate of drops per minute for periods of up to 60 hours.

Only in the first case did a transfusion stop of it accord. A needle was used in the catheter connexion, t with a very short catheter. The patient was restless a catheter was forced up until the needle was also in the Both catheter and vein were punctured and a hæm resulted. This difficulty has been overcome by the a longer catheter and the modified cannula already de

In one case we have given by this method th cells from 6 pints, and in another, 7 pints of whole Splinting has been unnecessary and the drip con to run when the patients' arms are folded. One n patient twice got out of bed without interfering cases where application has been made, dollars have forthcoming.

Extra Food for Blood Donors

LOUIS COMYNS asked the Minister of Food if he would ler the possibility of granting extra food points as an ragement for blood donors.—Dr. EDITH SUMMERSKILL d: Blood donors are never asked to give blood sufficiently ntly to impair their nutritional state. They are, of , given refreshments at the blood-transfusion centres. he Ministry of Food makes allowances of tea, sugar, and biscuits to the centres.

Tuberculosis in the Navy

plying to a question Mr. W. J. EDWARDS, parliamentary ary to the Admiralty, gave the following figures of the nce of tuberculosis in the Royal Navy.

rs and Men invalided for Pulmonary Tuberculosis ing the years 1940–46	9010
accepted by the Ministry of Pensions during the rs 1940–46	9614*
ttributable	3777
gravated	5837
s during service	430

ndes post-discharge claims from men invalided for reasons ther than tuberculosis.

Health Benefits for Foreigners

ptain JOHN CROWDER asked the Minister whether his ations entitled foreign nationals on a short visit to t Britain to full benefit under the National Health me, including the replacement of dentures or spectacles.— BEVAN replied: Yes.

Visitors to Ulster

r RONALD ROSS asked the Minister what arrangements d made for those registered under the National Health of Great Britain and Northern Ireland, respectively, h in that portion of the United Kingdom to which the under which they are registered does not apply.—Mr. AN replied: So far as Great Britain is concerned, the fits of the National Health Service are fully available ersons from any parts of the United Kingdom or else- re. As regards Northern Ireland, where the health ice is provided under an Act of the parliament of Northern and, I understand that arrangements have been or are g made for the service to be available to persons normally dent in Great Britain.

Health Centres

Sir HENRY MORRIS-JONES asked the Minister how many lth centres had been set up under the National Health vice Act; and whether he had any plans for the establish- of further centres in populous areas.—Mr. BEVAN replied: dispensaries from which general medical and dental vices were provided before July 5 are continuing as health ntres under the Act. I have approved a proposal to build centre on a developing housing estate in London; and the ovision of centres in other populous areas is under nsideration.

Fees for Ophthalmologists

Sir ERNEST GRAHAM-LITTLE asked the Minister if he was are that by the regulations S.I. 1273, 1948, and the state- nt specifying fees and charges for sight-testing opticians, e specialist ophthalmic surgeon, with at least ten years' dy before undertaking practice, would be at a monetary advantage as compared with the optician, who had had no mparable training, as in the example submitted to him; d if he would reconsider this position.—Mr. BEVAN replied: do not accept the assumption underlying the question. e remuneration of ophthalmic medical practitioners taking rt in the supplementary eye service has been fixed, in agree- nt with the profession, in the light of the Spens report the remuneration of consultants and specialists. The muneration of opticians for the supply and fitting of glasses approximately equal to the remuneration they received for e same services under the National Health Insurance heme.

Cost of Prescriptions and Spectacles

Sir HENRY MORRIS-JONES asked the Minister whether he would state the estimated cost of prescriptions dispensed under the National Health Service Act, and also the cost of supplying spectacles.—Mr. BEVAN replied: The estimated cost of prescriptions dispensed from July 5 to Aug. 5 is nearly £1,500,000. The amount paid from July 5 to Aug. 31 for sight-testing and supplying glasses under the supplementary ophthalmic service was £237,433, though this figure does not represent the full liabilities incurred during the period.

Cost of Dental Treatment

Sir ERNEST GRAHAM-LITTLE asked the Minister the cost to date of dental estimates submitted or approved by the Dental Estimates Board.—Mr. BEVAN replied: The board has authorised payment of a total of £708,307 up to Sept. 17.

Artificial Insemination

Mr. T. E. DRIBERG asked the Minister what facilities for artificial insemination were provided at clinics under the National Health Service; if such facilities included both A.I.(H.) and A.I.(D.); what information he had received from such clinics regarding the physical and mental health and development of children born as a result of artificial insemination; and if he would also make inquiries on this subject from private clinics.—Mr. BEVAN replied: No such facilities are provided. On the last part of the question I am not advised that such an inquiry would be justified.

Foot Clinics

Mr. SOMERVILLE HASTINGS asked the Minister why he had decided to discourage local authorities from opening foot clinics seeing that section 28 (1) of the National Health Services Act empowered these authorities to make arrangements for the purpose of the prevention of illness and that chiropody was essentially a preventive service.—Mr. BEVAN replied: I do not want to plunge into a general chiropody service without more advice. But I have told authorities that if experience shows the need they can put in proposals to me.

Spate of Prescriptions

Sir WALDRON SMITHERS asked the Minister if he was aware that the dispensation of doctors' prescriptions had, since the introduction of the health service, increased by more than 100%; and what steps he was taking to meet this situation.— Mr. BEVAN replied: I am not aware that chemists generally are experiencing difficulty in coping with the increased volume of dispensing.

Obituary

WILLIAM FREDERIC HARVEY

C.I.E., M.A., M.B. EDIN., F.R.C.P.E.

Lieut.-Colonel Harvey, who died in Edinburgh on Sept. 11 at the age of 76, was one of the original members of the Medical Research Department in India, where he gained a solid reputation both as investigator and administrator. Soon after his retirement in 1925 he joined the staff of the research laboratory at the Royal College of Physicians of Edinburgh, and for the many remaining years of his life he went on doing valuable work, especially on the structure and classification of new growths.

Born in 1873, he spent his childhood in India, where his father was an educational missionary in Travancore State. He returned to this country to go to school at Dollar Academy, and he continued his education at Edinburgh University and University College, London. In 1897 he graduated in medicine, with first-class honours, at Edinburgh, and two years later he joined the Indian Medical Service.

The following 27 years, which he spent in India, coincided with a time of widening opportunities for research in tropical medicine, and Harvey took full advantage of them. As an officer on probation he had already met Almroth Wright, who then held the chair of bacteriology at Netley, and later while on leave he worked in Wright's laboratory at St. Mary's. He was a great admirer of Wright's method, and when appointed deputy sanitary commissioner in the Punjab in 1902 he made many improvements in the manufacture and distribution of

Parliament

Army Cadets' Deaths from Heat-stroke

A STATEMENT circulated by Mr. EMANUEL SHINWELL, Secretary of State for War, includes the following information about the death from heat-stroke of two officer cadets at Aldershot after a physical-training exercise held on July 26, 1948.

The exercise was the fourth of a graduated series of physical-endurance exercises which formed a normal part of a physical-training syllabus designed, among other things, to make the cadets physically tough. Exercises of this type (though more severe) were introduced in 1942. They were made somewhat less exacting in 1944 and again in 1946, the latter change being the result of a fatality somewhat similar to this one. No other fatality has been reported during the last six years.

The exercises have been carried out in the past in all sorts of weather. The heat on this occasion, though exceptional, should not, taken by itself, have justified any major modification. Certain factors, however, combined to make the other conditions unusual. A strenuous morning's work, which took longer than was expected, was followed by a late lunch. The exercise was delayed and one instructor only—instead of two—could be made available.

The exercise started shortly after 3 P.M. The instructor, a sergeant, led the troop. After six miles they became somewhat strung out, and the instructor, hearing that one officer cadet had collapsed, called a halt; but, being informed that assistance had been summoned from barracks, he continued the exercise. An ambulance was summoned by telephone, but by an unfortunate chance was deflected to deal with another accident, and by the time it picked up the officer cadet some 35 or 40 minutes had elapsed. In the meantime a second officer cadet had collapsed. Cadets who were with him summoned help, and he was also collected by ambulance. Both cadets died the following morning, the cause of death being heart-failure due to heat-stroke.

"I am satisfied," Mr. Shinwell said, "that no officer or man can be charged with culpable negligence. It has been my object, however, to see that the instructing staffs at these schools should be specially picked and should realise that they have a special and important relationship to the young men in their care. I came to the conclusion that certain officers who were directly responsible for the exercise showed lack of judgment in allowing the exercise to proceed in the afternoon of such a hot day, after a strenuous morning and a rushed midday meal, and without the proper complement of instructors. I have accordingly ordered that they shall be replaced in their appointments."

A third officer cadet died after an exercise at Ripon.

The exercise was one of the standard physical-efficiency tests which are carried out once a year by all officers and men of Service units who are under 35 years of age and physically fit. This cadet had been passed medically fit for all duties on June 19.

July 28 was an unusually hot day, and in view of the heat the officer commanding the officer cadet squadron to which he belonged ordered that the officer-in-charge of the test was to take it easy and not to force the pace at all or allow the men to try to complete the course ahead of time. Also because of the heat the cadets were allowed to carry or wear steel helmets as they wished. The cadets had had an easy morning, chiefly lectures, and were not at all rushed.

The party undergoing the test consisted of about 40 cadets under an officer, assisted by a physical-training instructor and one sapper who was under training to become an instructor. The party marched for the first 5 or 6 miles; after this the officer-in-charge thought that a number of cadets would not finish the course in the time allotted, and allowed them to fall out and follow independently or to make their own way back to camp. Two cadets were sent back to the camp by car, and on arrival there an ambulance was sent to collect those who had fallen out.

Meanwhile, after about 8 miles, this officer cadet, who was among those who were straggling behind, became very distressed and collapsed. He was left under the charge of the instructor, who took him by ambulance to the camp reception station, where he arrived 45 minutes later. The medical officer-in-charge decided that the only course was to get him to York Military Hospital as quickly as possible. Emergency treatment was begun at once and was continued medical officer in the ambulance all the way to York, he arrived at 6 P.M., some two hours after he had He died of heat-stroke shortly after midnight.

Mr. Shinwell concluded that "no-one was to b the tragic death of this officer cadet."

Adjournment

On Sept. 24 Parliament adjourned until M Oct. 25.

QUESTION TIME

The Common Cold

Mr. JOHN LEWIS asked the Lord President of the to what extent the Medical Research Council and similar organisations had been concerned during t year with investigation into the cause and cure of the cold; what sums had been expended on this research what results had been attained.—Mr. HERBERT M replied: The Medical Research Council, with the of the Ministry of Health, have continued to maintain into the nature and transmission of the infection human volunteers, at the Harvard Hospital, The cost to the council during the last financial approximately £9500, exclusive of hospital acco and services provided by the Ministry of Health. progress has been made, but there are as yet no capable of practical application. Mr. LEWIS: Is totally inadequate sum being spent on investigation this matter, which quite obviously is costing the many millions of pounds every year?—Mr. MORRI I was quite sure that by going to the Treasury and for a substantial addition we would automatically problem, I would do so; and I agree that it w But money spent upon research must be governed likely practical results from the expenditure. We all we can. Mr. LEWIS: How can one possibly say the likely results will be unless money is spent on —Mr. MORRISON: That is a very wasteful philoso

World Health Assembly and Mental He

Mr. FRANCIS NOEL-BAKER asked the Minister of whether he was satisfied that the composition of the delegation to the World Health Assembly was su enable it to play an adequate part in discussions re psychiatry and mental health; and whether l consider strengthening British delegations to future of the organisation by the inclusion of experts in subjects.—Mr. ANEURIN BEVAN replied: This assem little concerned with technical discussion of psychia mental health. I shall certainly have in mind i an expert in these subjects in any future delegations I am clear the probable subject matter warrants it.

Compensation on Resignation from N.H.S.

Sir ERNEST GRAHAM-LITTLE asked the Minister w in the event of a doctor electing to resign from the N Health Service shortly after entry, and having giv necessary three months' notice of resignation, his compe for loss of practice goodwill will be payable; and withi waiting period.—Mr. BEVAN replied: Payment will be as soon as the information is available on which the a due can be calculated. Meantime, a payment on a will be made if hardship would otherwise be involved

Apparatus for Cancer Research

Air Commodore A. V. HARVEY asked the Chance the Exchequer if he was satisfied that sufficient U.S cu had been made available to enable modern equipmen purchased for the treatment of cancer.—Mr. GLENVII replied: It has been agreed with the British Empire Campaign that dollar exchange will be made availa the purchase of any scientific apparatus essential for research which can only be obtained from the United Air Commodore HARVEY: Is the Minister aware tha is a feeling in the medical profession that for much equ which is required dollars are not available, and i requests are made to the Bank of England will he i the Bank to deal with these applications favoura Mr. HALL: My information is that everything is v very smoothly. We have had no complaints wh

n outbreak of gastro-enteritis investigated by us winter 1946–47 and reported to the British tric Association (James 1947) *Proteus vulgaris* was d from the stools in every case and believed to part in the ætiology. *P. morganii* and organisms salmonella and shigella groups were excluded.

iew of these findings and of reports from elsewhere treptomycin given by mouth produces bacterio- throughout the gut, and that naturally occurring s of *P. vulgaris* are usually sensitive to streptomycin, ned logical to give streptomycin by mouth in cases of -enteritis associated with *P. vulgaris* in the stools were not responding to routine treatment. It emed important to establish whether streptomycin by mouth was of any value in cases where *lgaris* was not found in the stools. Therefore such its were given streptomycin by mouth when routine nent was unsuccessful and the prognosis was grave. tiological factors in these cases were not known.

April, 1947, as a preliminary investigation, strepto- was given by mouth to two infants with mild œa associated with *P. vulgaris* in the stools. was done solely to determine whether the organism be eliminated from the stools by this method, he enteritis was so mild that these cases are not led in the present series.

is report is based on thirty treated cases, which are dered in three categories :

up A : cases from an outbreak of epidemic diarrhœa newborn.

up B : cases from an outbreak of gastro-enteritis in a ntial nursery.

up C : cases of gastro-enteritis in this Children's Unit, ding patients critically ill on admission and cases not nding to routine treatment.

outine treatment of all cases, except those in group C cally ill on admission, consisted of an initial period tarvation for 24 hours, during which sterile water e was given by mouth, followed by the gradual ding up of milk feeds at the rate of 60 calories a When possible, expressed breast-milk was given ; rwise half-cream or full-cream National Dried Milk used according to the age of the child. All feeds e made up to 20 calories to the ounce, and extra r was given as needed. Sugar was not added to feeds until the 3rd or 4th day. When intravenous s were indicated, one-fifth physiological saline with glucose or a quarter physiological saline with 2·5% ose was used ; and, if intravenous therapy was inued for longer than 24–48 hours, protein hydro- te solution supplemented the glucose-saline solution. mins by mouth were not given until full feeds had reached.

osage of Streptomycin by Mouth.—To maintain a tant bacteriostatic concentration, the total daily of streptomycin was dissolved in sterile water, and an l fraction was given immediately before each feed.

ases 10 and 20 were given a total of 2 g. in 4 days. iew of the scarcity of streptomycin and the early disappearance of *P. vulgaris* from the stools it was hoped that a smaller dose would be adequate, and cases 12 and 13 received 1 g. in 4 days. However, the organism reappeared in 2 days ; therefore all other cases were treated with 2 g. in 7 days : 0·5 g. in the first 24 hours, and 0·25 g. in each subsequent 24 hours for a further 6 days. The higher initial dose was given because of the known tendency of organisms to become resistant to streptomycin in a short time.

It was found convenient to make up the streptomycin solution so that the fraction of the daily dose to be given before each feed was contained in 1 ml. The solution was given with a spoon or a pipette, or direct from the hub of a syringe, and appeared to be palatable. No vomiting could be attributed to the streptomycin.

We found that the children having streptomycin tolerated milk feeds well, and that these could be increased at the rate of 100 calories a day. When streptomycin was started during the later stages of routine treatment, no further period of starvation was necessary, and the feeds could be increased at the rate of 100 calories a day from the level already reached.

GROUP A : EPIDEMIC DIARRHŒA OF THE NEWBORN

An epidemic of diarrhœa broke out in a maternity hospital. Fig. 1 shows the progress of four treated cases compared with that of twenty-three control cases occurring in the same period and receiving routine treatment only. The four cases selected for streptomycin therapy were the most severe in the outbreak. Jaundice had developed in three of them on the 18th, 34th, and 7th days of life.

CASE 1 was a premature infant weighing at birth 3 lb. 3 oz. Diarrhœa started on the 20th day of life, the latest onset in this group. Stool cultures were negative, and after 19 days' routine treatment (two periods of starvation followed by increasing feeds with an interval of 7 days during which she had full feeds) there was a sudden deterioration in her condition, and she appeared moribund. Her response to streptomycin was dramatic, and she regained her greatest previous weight (a gain of 13 oz.) in 10 days.

CASES 2 and 3 were selected for streptomycin treatment because of the severity of the gastro-enteritis, the lack of response to routine treatment, and the development of jaundice.

CASE 4 did not become jaundiced, but the combination of dehydration with œdema and the lack of any response to routine treatment prompted the administration of streptomycin.

The average number of days taken to regain the greatest weight reached before the illness was 12 in the treated cases compared with 25 (minimum 12, maximum 43) in the twenty-three less severe cases (fig. 1).

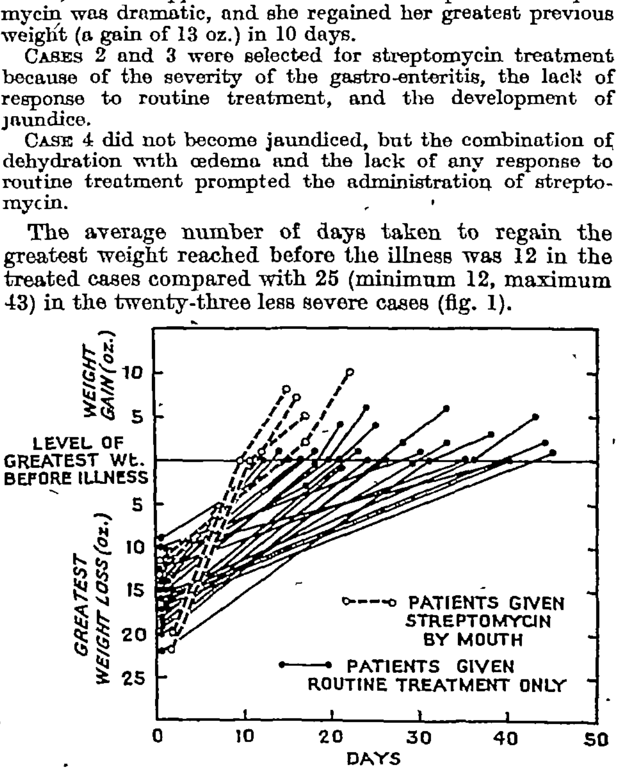

Fig. 1—Rates of return from points of greatest loss of weight to greatest weight reached before illness in epidemic diarrhœa of newborn (group A).

vaccine lymph and introduced glycerinated lymph into the province. Another lasting influence on his approach to medical problems was Karl Pearson, from whom he derived his critical approach to research.

When the government of India constituted the Medical Research Department (or Bacteriological Department as it was first called), Harvey was one of the first group of officers, which included Bannerman, Semple, Lamb, Lieut.-Colonel Glen Liston, Sir Rickard Christophers, S. P. James, and A. G. McKendrick who became his lifelong friend. His first post in the new department was as assistant director of the Pasteur Institute of India, and in 1905 he succeeded Lamb as director. McKendrick became his assistant and together they carried out the researches into the prevention of rabies which led to the introduction of Semple's carbolised vaccine.

In 1911 Harvey was appointed director of the Central Research Institute at Kasauli, where he devoted himself largely to bacteriological and immunological problems, particularly methods of technique. On these subjects he published many papers in the *Indian Journal of Medical Research*, of which he was the first editor when it was founded in 1913. His work was interrupted by the first world war; for in 1916 he was recalled to military service and appointed an A.D.M.S. in Mesopotamia. There he was one of the officers called upon to reorganise the medical side of the Army after the earlier campaigns, and his work won a mention in despatches. After an attack of paratyphoid fever he was invalided to India and he returned to Kasauli till he retired in 1925. He was appointed C.I.E. in 1921. Of this part of his career a colleague says: "Harvey was very much liked by all who came in contact with him, and his advice was freely sought and readily given on all subjects connected with research in India. He was always constructive in his criticisms of any work on which his counsel was sought."

'Settling in Edinburgh, Harvey in 1927 succeeded James W. Dawson as histopathologist to the laboratory of the Royal College of Physicians of Edinburgh. The results of this new work appeared in the next 20 years in his papers in the *Edinburgh Medical Journal*, on such subjects as the standardisation of blood examination, irradiation effect on the skin, carcino-sarcoma, and chordoma. His series of studies, in collaboration with E. K. Dawson and J. R. M. Innes, on debatable tumours in human and animal pathology, were later issued as a monograph. For a short time he took Colonel McKendrick's place as superintendent of the laboratory, and he continued the heavy routine reporting involved by war conditions until 1946 when he was freed to continue his tumour studies.' For his work the college awarded him the Lister and Freeland-Barbour fellowships and in 1946 the Cullen prize. He represented the college on the Imperial Cancer Research Fund committee and he was also a vice-president of the Royal Society of Edinburgh and a section editor of the *Tropical Diseases Bulletin*.

Sir Rickard Christophers writes: During his time in India Colonel Harvey played an important part in the development of the bacteriological service and especially in the expansion of the activities of the Central Research Institute, Kasauli, the government research laboratory. Not only was he an able bacteriologist and research-worker but he had high capabilities as an administrator, and many who have worked under him as director will remember his unfailing sympathetic and helpful advice and staunch support where such was needed. Though of a somewhat retiring disposition, he had a great gift of making loyal and lasting friends. He was a man of wide interests and many activities, and one of his outstanding characteristics was the thoroughness with which he carried out any work he undertook. In such cases no labour was too great and the object was pursued with a doggedness which usually achieved its end. As an example, when on retirement he became engaged in reviewing papers for a certain journal he surprised his friends by learning Dutch, and as a result must have been one of the very few British research-workers in his line who could read Dutch scientific papers in the original. After retirement and when working in the Edinburgh Pathological Diagnosis Laboratory he so developed his knowledge of tumours that he became a recognised authority on this subject. With this he was pleasant hospitable friend, a keen tennis-player great social acquisition. Many will regret his who knew him at his station in Kasauli more kindly local magnate than the hard-working

Colonel Harvey married in 1910 Miss Jean They had a daughter and a son who is also a doctor.

Births, Marriages, and Deaths

BIRTHS

Barclay.—On Sept. 15, at Waltham Abbey, the wife of Barclay, F.R.C.S.—a son.

Cox.—On Sept. 25, in London, the wife of Dr. A. G. C. Co

Danckwerts.—On Sept. 21, at Kenilworth, the wife of Dr. Danckwerts—a daughter.

Eden.—On Sept. 16, at Vancouver, British Columbia, of Dr. John Eden—a daughter.

Elmes.—On Sept. 20, at Sherborne, the wife of Dr. B. G. T. a daughter.

Gareh.—On Sept. 20, at Harrow, the wife of Major R.A.M.C.—a son.

Gowar.—On Sept. 20, at Aberdeen, the wife of Mr. F. J. Gowar, V.R.D., F.R.C.S.—a daughter.

Hardy.—On Sept. 18, at Truro, the wife of Dr. J. D. a daughter.

Harman.—On Sept. 25, in London, the wife of Dr. J. B. —a daughter.

Inkster.—On Sept. 17, at Stockton-on-Tees, the wife of J. S. Inkster, R.A.M.C.—a daughter.

Kidd.—On Sept. 14, at Grendon Underwood, Bucks, the Dr. Humphry Kidd—a daughter.

Lovett Doust.—On Sept. 19, in London, the wife of Dr Lovett Doust—a daughter.

MacLeod.—On Sept. 21, at Clevedon, Somerset, the wife Alastair MacLeod—a daughter.

Nairac.—On Aug. 31, in Mauritius, the wife of Dr. M. L. —a son.

Pierce.—On Sept. 21, in London, the wife of Dr. John a daughter.

Rollason.—On Sept. 27, at Scunthorpe, the wife of Dr. Rollason—a son.

Scott.—On Sept. 18, in London, the wife of Dr. I. M. Scott a son.

Thoms.—On Sept. 22, at Bognor Regis, the wife of Commander Geoffrey Thoms, R.N.—a son.

Venning.—On Sept. 25, in London, to Dr. Ruth Venning Barker), wife of Dr. G. R. Venning—a son and a daughter.

MARRIAGES

Lees—Fawcus.—On Sept. 18, at Aston Clinton, Bucks, Lees, M.B., to Pamela Joan Fawcus.

Wetherell—Mann.—On Sept. 18, at East Budleigh, Wetherell, M.B., to Rosemary Mann.

DEATHS

Boulton.—On Sept. 19, Norman John Boulton, M.R.C.S., aged

Fisher.—On Sept. 25, at Barnton, Midlothian, Edward Fisher, M.B. Lond., F.R.C.S., M.R.C.P.E., D.P.H.

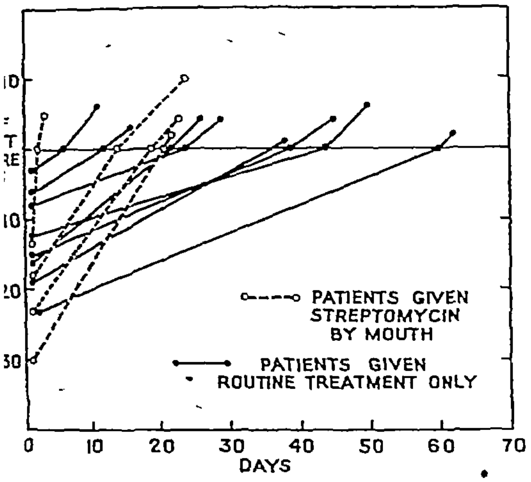
Gavronsky.—On Sept. 24, Jacob Osip Gavronsky, M.D. aged 70.

Ghosh.—On Sept. 24, at Salford Royal Hospital, Ghosh, F.R.C.S.I., D.P.H., aged 61.

Gibson.—On Sept. 16, Harold Edward Gibson, M.A., D.M. Oxfd.

Potts.—On Sept. 25, at Woking, Surrey, Edmund Thurlow C.M.G., D.S.O., M.D. Edin., lieut.-colonel, R.A.M.C. retd.

Shubik.—On Sept. 20, 1948, at Oxford, Nancy Gwendolyn M.R.C.S., D.P.H.



ites of return from points of greatest loss of weight to greatest reached before illness in an epidemic of gastro-enteritis in a tial nursery (group B).

l of these times each child was deteriorating, stro-enteritis continuing, and the weight stili Streptomycin 2 g. in 7 days was then given uth in the way described, and all three cases led well and quickly (fig. 4).

8, aged 11 months, had been in hospital with gastro- s before admission to the nursery. On admission he ny and lethargic and seemed mentally backward. minor recurrent attacks of passing loose offensive nd lost 4–14 oz. with each bout. Even between attacks ols tended to be pale and bulky, and *P. vulgaris* was from them repeatedly. Streptomycin was given by during one of these episodes, his weight gain was hing, and his stools became normal in 5 days and have ed so. He has had no further gastro-enteritis, and his progress has been dramatic. He is now (10 weeks normal child for his age (fig. 5).

average recovery-rate in these four cases was lays—considerably shorter than that of the less ly ill controls:

	Controls	*Treated*
e weight loss (oz.)	12 6	21·5
e recovery-rate (days)	30 75	11·4
aris present in stools	5	4
aris absent from stools	2	0
not examined	1	0
e time for stools to become al after streptomycin (days)	12 2	3·8
	2 wk. to 1¼ yr.	3 to 7 mos.

this group it seems certain that streptomycin py speeded up recovery. Two patients were ally ill when it was started; one was not seriously it was not improving on routine treatment; and ourth child had recurrent diarrhœa and was probably ource of infection in the nursery outbreak.

GROUP C: GASTRO-ENTERITIS IN THE CHILDREN'S UNIT

nts Critically Ill on Admission

es 9, 10, and 11 were admitted in a critical condition gastro-enteritis, and it was thought unwise to spend in giving routine treatment alone.

E 9, a boy aged 4 months, was admitted from another al, where he had been treated for gastro-enteritis and ad 4 serious relapses in 24 days. On each occasion he had tarved and given intravenous and intraperitoneal fluids. ting was copious, and his 5–8 stools a day were large, and offensive. His weight loss was over 2 lb. 3 oz. o parenteral fluids (his greatest weight before illness ot known). Oral streptomycin was started, and feeds calories in the first 24 hours with additional water) given by mouth and retained, no further parenteral being required. The stools improved and were normal days, the feeds being increased by 100 calories a day. atient was fit for discharge 10 days after admission but had to remain in hospital another 10 days because of housing difficulties. During his 3 weeks' stay he gained 2 lb. and he gained a further 2 lb. in the 3 weeks following his discharge (fig. 6).

CASE 10, a boy aged 5 weeks, was admitted with severe gastro-enteritis of 2 days' standing. He had been offered full feeds but had taken only a few ounces in these 48 hours. His vomiting was copious, and the stools were large and entirely fluid (8 having been passed in the 10 hours before admission, and 12 in the 24 hours before that). On admission he was cold, collapsed, semiconscious, and grossly dehydrated. Intravenous fluids (2·5% glucose in *N*/4 saline) and streptomycin by mouth were given immediately. Water was given by mouth, and milk feeds were started 12 hours later, these being increased at the rate of 100 calories a day. Vomiting ceased after the first dose of streptomycin, and no further parenteral fluids were needed. No stools were passed for 48 hours. The patient's recovery was uneventful, and he was discharged 9 days after admission, having gained 25 oz. (fig. 6).

CASE 11, a girl aged 8 months, was transferred from a voluntary hospital, where routine treatment with intravenous fluids had been given for gastro-enteritis of 6 days' standing, this treatment being in accordance with our schedule. Her condition was considered hopeless; she had retained no fluids by mouth for 6 days, and was having copious fluid stools. She took streptomycin by mouth well and had no further vomiting, her stools improving in 3 days. Feeds were started on the 1st day, beginning at 100 calories and increasing to full feeds in 6 days. She was discharged 12 days after admission, having gained 20 oz., and a month later she had gained a further 4 lb. (fig. 6).

These were the only patients in the series to be given streptomycin on the day of admission. The speed of their response to streptomycin therapy was spectacular, and two of them needed no further parenteral fluids. They were ready for discharge in 9, 10, and 12 days.

Cases not Responding to Routine Treatment

The nineteen patients in this group were aged from 9 days to 13 months and were either admitted with gastro-enteritis or developed it in hospital. Five patients were under 3 months old and were all admitted with gastro-enteritis. Cases 12 and 13 were premature twins with birth weights of 4 lb. 4 oz. and 2 lb. 15 oz., and both developed gastro-enteritis within a few days of each other when 6 weeks old. Both responded well to streptomycin, not having improved on several days' routine treatment (fig. 7).

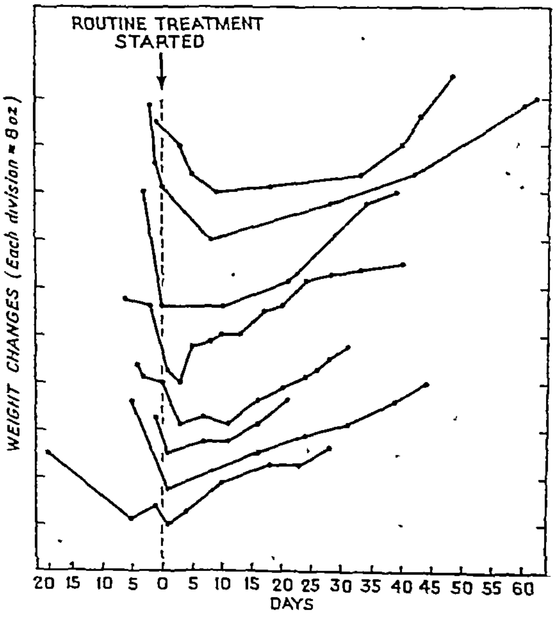


Fig. 3—Weight changes in 8 controls (group B).

GROUP B: EPIDEMIC GASTRO-ENTERITIS IN A RESIDENTIAL NURSERY

An epidemic of gastro-enteritis broke out in a residential nursery among infants under 2 years of age, twelve children being affected.

The controls consisted of eight cases of moderate severity in infants aged from 2 weeks to $1^3/_4$ years. They were given routine treatment. The loss of weight was 3–23 oz. (average 12·6 oz.), and the recovery-rate (time taken to regain the greatest weight reached the illness) was 6–60 (average 30·75) days (accompanying table and figs. 2 and 3). In five the eight cases *P. vulgaris* was isolated from the All these children recovered, but their progress

The treated patients numbered four and 3–11 months. Cases 5, 6, and 7 were much more ill than any of the controls. They each received treatment for 11, 5, and 4 days respectively,

RESULTS OF TREATMENT OF INFANTILE GASTRO-ENTERITIS WITH STREPTOMYCIN BY MOUTH

Group		Case no.	Sex	Age on admission	Birth weight before treatment		Max. weight before treatment		Max. weight loss		Length of history before admission (days)	Duration of routine treatment (days)	Clinical condition				Complications	Bacteriology of stool	General progress

GROUP C: GASTRO-ENTERITIS IN THE CHILDREN'S UNIT

nts Critically Ill on Admission

ses 9, 10, and 11 were admitted in a critical condition gastro-enteritis, and it was thought unwise to spend in giving routine treatment alone.

E 9, a boy aged 4 months, was admitted from another al, where he had been treated for gastro-enteritis and nd 4 serious relapses in 24 days. On each occasion he had starved and given intravenous and intraperitoneal fluids. ting was copious, and his 5–8 stools a day were large, and offensive. His weight loss was over 2 lb. 3 oz. o parenteral fluids (his greatest weight before illness ot known). Oral streptomycin was started, and feeds calories in the first 24 hours with additional water) given by mouth and retained, no further parenteral being required. The stools improved and were normal days, the feeds being increased by 100 calories a day. atient was fit for discharge 10 days after admission but had to remain in hospital another 10 days because of housing difficulties. During his 3 weeks' stay he gained 2 lb. and he gained a further 2 lb. in the 3 weeks following his discharge (fig. 6).

CASE 10, a boy aged 5 weeks, was admitted with severe gastro-enteritis of 2 days' standing. He had been offered full feeds but had taken only a few ounces in these 48 hours. His vomiting was copious, and the stools were large and entirely fluid (8 having been passed in the 10 hours before admission, and 12 in the 24 hours before that). On admission he was cold, collapsed, semiconscious, and grossly dehydrated. Intravenous fluids (2·5% glucose in *N*/4 saline) and streptomycin by mouth were given immediately. Water was given by mouth, and milk feeds were started 12 hours later, these being increased at the rate of 100 calories a day. Vomiting ceased after the first dose of streptomycin, and no further parenteral fluids were needed. No stools were passed for 48 hours. The patient's recovery was uneventful, and he was discharged 9 days after admission, having gained 25 oz. (fig. 6).

CASE 11, a girl aged 8 months, was transferred from a voluntary hospital, where routine treatment with intravenous fluids had been given for gastro-enteritis of 6 days' standing, this treatment being in accordance with our schedule. Her condition was considered hopeless; she had retained no fluids by mouth for 6 days, and was having copious fluid stools. She took streptomycin by mouth well and had no further vomiting, her stools improving in 3 days. Feeds were started on the 1st day, beginning at 100 calories and increasing to full feeds in 6 days. She was discharged 12 days after admission, having gained 20 oz., and a month later she had gained a further 4 lb. (fig. 6).

These were the only patients in the series to be given streptomycin on the day of admission. The speed of their response to streptomycin therapy was spectacular, and two of them needed no further parenteral fluids. They were ready for discharge in 9, 10, and 12 days.

Cases not Responding to Routine Treatment

The nineteen patients in this group were aged from 9 days to 13 months and were either admitted with gastro-enteritis or developed it in hospital. Five patients were under 3 months old and were all admitted with gastro-enteritis. Cases 12 and 13 were premature twins with birth weights of 4 lb. 4 oz. and 2 lb. 15 oz., and both developed gastro-enteritis within a few days of each other when 6 weeks old. Both responded well to streptomycin, not having improved on several days' routine treatment (fig. 7).

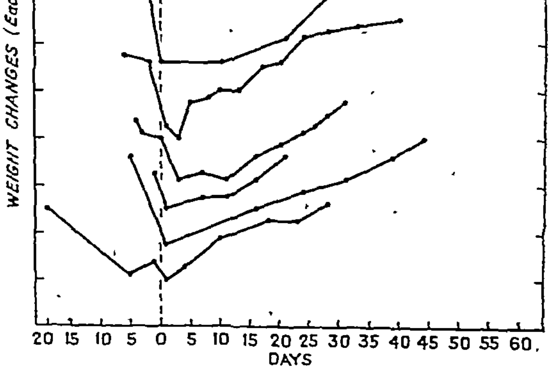

Fig. 3—Weight changes in 8 controls (group B).

GROUP B: EPIDEMIC GASTRO-ENTERITIS IN A RESIDENTIAL NURSERY

An epidemic of gastro-enteritis broke out in a residential nursery among infants under 2 years of age, twelve children being affected.

The controls consisted of eight cases of moderate severity in infants aged from 2 weeks to $1^3/_4$ years. They were given routine treatment. The loss of weight was 3–23 oz. (average 12·6 oz.), and the recovery-rate *(time taken to regain the greatest weight reached* the illness) was 6–60 (average 30·75) days accompanying table and figs. 2 and 3). In the eight cases *P. vulgaris* was isolated from the *All these children recovered, but their progress*

The treated patients numbered four and 3–11 months. Cases 5, 6, and 7 were much more ill than any of the controls. They each received treatment for 11, 5, and 4 days respectively,

* Recurrent gastro-enteritis.

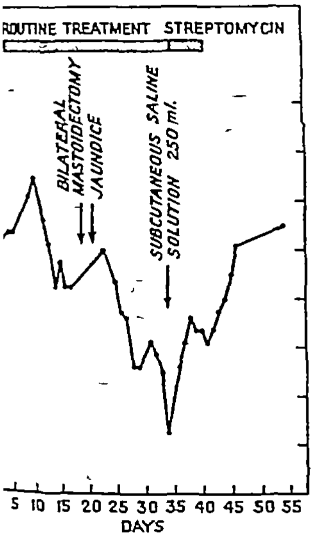
ed it in the ward, having been admitted with

25. After 5 days' routine treatment, during which a and vomiting persisted, a bilateral mastoidectomy ne and necrotic bone was found on one side, but from it remained sterile. The boy's symptoms con- and despite intravenous and subcutaneous saline ravenous protein hydrolysate, the weight loss over days was 4 lb. Streptomycin was given by mouth, overy was rapid and uneventful. In the week on nycin the patient gained 1 lb. 6 oz. (fig. 13).

ccompanying table shows the salient features of all ted cases.

SUMMARY OF RESULTS

ty-eight of the thirty cases described responded torily to streptomycin given by mouth. One 16) died, and another (case 18) had bilateral mastoiditis, which was treated surgically, the child's recovery being in no way attributable to streptomycin.



Weight changes in case 15 (group C), sponding to routine treatment or to ral mastoidectomy and given strepto- n by mouth.

Weight seemed to be the most reliable measurable index of a child's progress. Since intravenous and subcutaneous saline was seldom necessary after starting streptomycin therapy, the gains shown in figs. 1–13 were not influenced by parenteral fluids, except in cases 5 and 10. In some cases the weight continued to fall during the first 24 hours of treatment with streptomycin, but after the gains were spectacular. We considered ossibility of encountering these rapid gains in healthy ren given streptomycin. Three such children, 4, 5, and 10 months, were weighed daily for 14 the same diets being given throughout, and tomycin given by mouth in the same dosage as ar gastro-enteritis cases for the last 7 days. No rence was found in the rate of gain in the two weeks. gains in weight of the treated patients and of the rols are compared below.

ools.—In most cases improvement in the general ition preceded improvement in the stools. The istence of the stools improved rapidly, but frequency often persisted for 3 or 4 days, and they ined bulky and curdy for about 7 days. In cases e constipation developed after the administration of tomycin no increase in toxæmia was observed, in adistinction to that seen where diarrhœa is relieved chalk and opium.

hen streptomycin was given by mouth as described; was a rapid fall in the number of organisms in ut. In most cases a stage was reached, usually lasting few hours but occasionally for several days, when no th could be obtained aerobically from the stools. If *lgaris* was present it sometimes disappeared from the s in as short a time as 4 hours. Preliminary investiga- (by a method to be described elsewhere) showed the streptomycin content of the stools could be igh as 1·5–2 mg. (1500–2000 units) per ml. Then intestinal flora was gradually re-established, *Strep. fæcalis* often reappearing first and sometimes persisting in pure culture for several days.

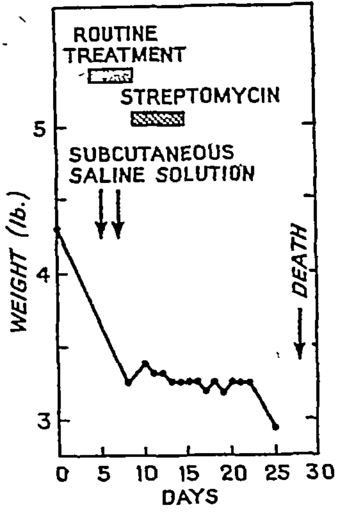


Fig. 9—Weight changes in case 16 (group C), not responding to routine treatment and given streptomycin by mouth. There were large amounts of blood in the stools.

It is important to bear in mind the possibility that organisms not usually present in the gut may become established there while the normal organisms are absent. One of us (I.R.H.K.) investigated the case of an infant given streptomycin by mouth who collapsed suddenly and died on the 3rd day of treatment. Cultures taken from the terminal ileum post mortem gave a pure growth of a streptomycin-resistant coagulase-positive *Staph. aureus*. The infant had a *Staph. aureus* conjunctivitis when streptomycin therapy was started.*

Vomiting ceased in most cases after the first dose of streptomycin, and the appetite improved early in the course of treatment. This early cessation of vomiting is one of the greatest assets in the use of streptomycin in gastro-enteritis.

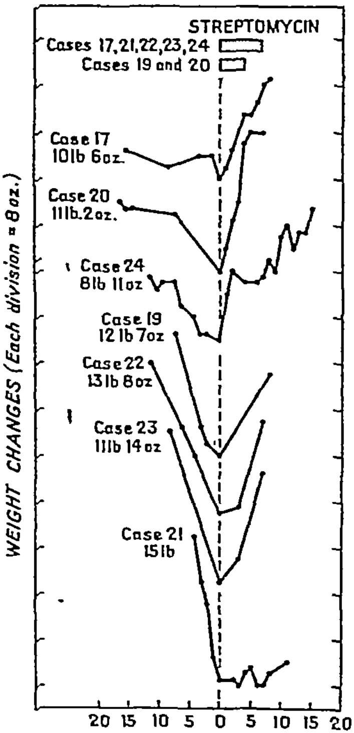

Fig. 10—Weight changes in 7 patients (group C) aged 3-5 months, not responding to routine treatment and given streptomycin by mouth.

Milk feeds were well tolerated when the child was having streptomycin, and it will have been noted that in the patients critically ill on admission to the Children's Unit, where streptomycin was given on the day of admission, feeds were given on that day at the level of 100 calories and increased by 100 calories a day. It is probable that, if cases were treated with streptomycin at the onset of gastro-enteritis, starvation could be safely omitted and generous feeds given throughout the illness.

Jaundice developed in five cases during routine treatment. It was most severe in case 15, when it lasted for 17 days, fading on the 4th day of the streptomycin course. All five patients recovered.

Stay in Hospital.—From the time that streptomycin was given, the patients' stay in hospital was very short. Most of them were fit to leave in 9–14 days, even in the most severe cases.

---

* This case is being described in detail in a later paper.—I. R. H. K.

CASE 14, a boy aged 2 months, had two recurrences of gastro-enteritis and did not respond to routine treatment during his third attack. The response to streptomycin was dramatic: he gained 10 oz. during the week, and his stools improved after 3 days, though they were still bulky and curdy 10 days later (fig. 7).

CASE 15, a girl aged 5 weeks, was one of the earliest cases treated. She had been admitted with a history of 4 days' diarrhœa and vomiting, and during the next 5 weeks she received rigorous treatment, including intravenous therapy, but she lost 2 lb. 2 oz. in weight. Her illness was complicated by bilateral mastoiditis (treated surgically) and pyelitis. She became deeply jaundiced, and her condition was critical. Her stool cultures were negative for *P. morganii* and *P. vulgaris* and for organisms of shigella and salmonella groups. All the patients previously treated had had *P. vulgaris* in their stools, but in view of the long period over which she had been treated and the gravity of her condition it was thought advisable to try streptomycin. Vomiting ceased from the 1st day, her stools improved, she needed no further parenteral fluids, and she gained 15 oz. during the week (fig. 8).

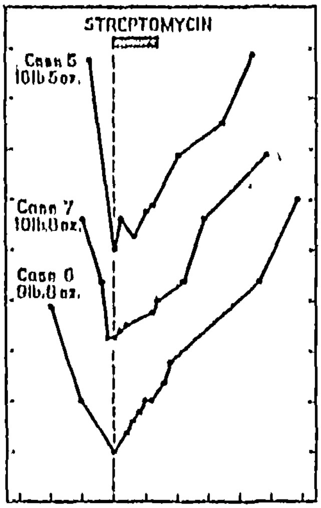

Fig. 4—Weight changes in 3 patients (group B) given streptomycin by mouth.

CASE 16, a girl aged 9 days, was admitted with 4 days' history of diarrhœa. Her stools had been frequent and fluid, and contained large amounts of bright blood. She was given routine treatment and injections of vitamin K with no improvement. Her total white-cell count at this time was 24,000 per c.mm. (eosinophils 24%). Streptomycin was then given by mouth and, though her diarrhœa and vomiting ceased and her general condition improved, she did not gain weight. She collapsed 7 days later, passed fluid stools containing large amounts of blood, and died in 24 hours (fig. 9). There had been no contact with other cases of diarrhœa, and her stool cultures were negative for all pathogenic organisms. Her father subsequently disclosed that he had had amœbic dysentery some time earlier but had not been in contact with the baby.

Necropsy (Dr. J. Bate) showed clear bloodstained fluid in the peritoneal cavity, the ileum intensely congested, and immediately proximal to the ileocæcal valve about 20 punched-out ulcers, most of them involving the mucosa only, but a few reaching the serous coat.

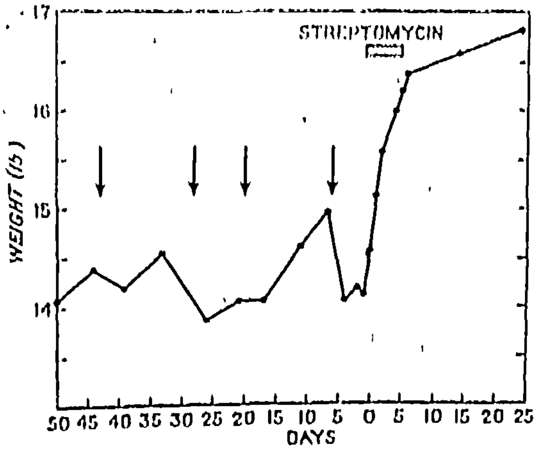

Fig. 5—Weight changes in case 8 (group B) given streptomycin by mouth: arrows indicate exacerbations.

This was the only case in the series with large of blood in the stools, but it is interesting to Loisli (1947) found this in 11 (23·0%) of hi

CASE 18 had had gastro-enteritis for a week, he had been admitted to another hospital. He improved and was transferred to us for tre streptomycin. Since his condition was not critical further routine treatment for another 6 days, with and he lost altogether 2 lb. 3 oz. Streptomycin by mouth, and next day a right otitis media Myringotomy was done and pus released. Five there was reddening and bulging of the left tympanic membrane, and myringotomy was done. During these 5 days he improved, the diarrhœa and vomiting lessened, and he gained 18 oz. In the subsequent 24 hours he lost 8 oz. and began to vomit again. Bilateral mastoidectomy was done, pus being found on both sides and *Bact. coli* obtained in pure culture from the right side. The patient's subsequent progress was satisfactory (fig. 11).

In case 18 the recurrence of diarrhœa and vomiting was due to the parenteral infection, and this should have been recognised and treated before streptomycin was considered. In the presence of such an infection streptomycin by mouth is valueless.

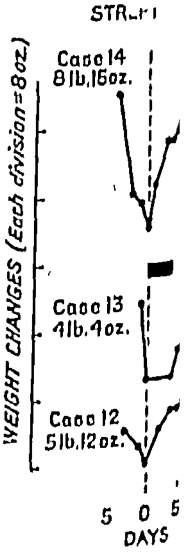

Fig. 7—Weight changes (group C) aged less th not responding to ro ment and given mouth.

There were six patients aged 6 months or more, none of whom had improved on routine treatment for a maximum of 17 days, a mini 4 days, and an average of 9 days (fig. 12 were admitted with gastro-enteritis, and one

e results indicate a real improvement in the treated

SUMMARY

ptomycin was given by mouth in thirty cases of
le gastro-enteritis. Its effects were most striking
critically ill cases, in cases of recurrent diarrhœa
miting, and in neonatal gastro-enteritis. Vomiting
early, weight was rapidly gained, the appetite
ed, the stools improved, and there was almost
iate improvement in the general condition.

ptomycin 2 g. by mouth in 7 days was given
t producing toxic effects. It was palatable
ell tolerated, even where there had been copious
ing.

administration of streptomycin by mouth does
obviate the necessity of treating parenteral
ion, which may play a part in the causation of
-enteritis.

re is a danger that pathogens remote from
it may be rendered streptomycin-resistant by the
amount of streptomycin that enters the blood-
n.

ptomycin by mouth effectively eliminated *Proteus*
is from the stools and was also effective in cases
tro-enteritis where no pathogenic organisms were

ptomycin by mouth shortened the course of gastro-
tis to a considerable extent, the usual time of
rge from hospital being 9–14 days after the start
atment, even in the very severe cases. This is a
asset in alleviating the pressure on beds and
ing the risk of cross-infection.

early administration of streptomycin by mouth
tro-enteritis may make it possible to omit a period
rvation and to give generous feeds throughout the

It is not expected that all types of gastro-enteritis of unknown ætiology or those of virus origin will respond to streptomycin given by mouth.

We wish to thank the Medical Research Council's streptomycin trials committee for non-tuberculous diseases for the supplies of streptomycin: Sir Alexander Fleming and Dr. W. H. Hughes for their unfailing encouragement; the resident medical officers, nurses, and laboratory technicians who have contributed so much to this investigation; and Mr. P. Armitage for his statistical analysis.

SURVIVAL PERIOD OF PATIENTS WITH CEREBRAL HÆMORRHAGE DYING IN HOSPITAL

W. McI. Rose
M.D. Melb., M.R.C.P., M.R.A.C.P.
From the Department of Pathology and Bacteriology, University of Leeds

In his classical paper on sudden death Spilsbury (1917) says that cerebral hæmorrhage is rarely a cause. This statement is generally accepted, for it accords with common clinical experience. But very little seems to have been written about the duration of life after cerebral hæmorrhage has occurred. Aring and Merritt (1935), in an article on the differentiation of hæmorrhage and thrombosis, pay scant attention to this point, and Newbill (1940) is content to state that hæmorrhage is more apt to be responsible when death takes place within twenty-four hours of the onset of symptoms.

My object here is to provide information about the duration of life after spontaneous cerebral hæmorrhage, including that from the rupture of an intracranial aneurysm. This is not of academic interest only, for early differentiation between hæmorrhage and thrombosis is necessary for effective use of systemic anticoagulants, as well as in assessing the results of treatment.

My facts are taken from the clinical and post-mortem records of the General Infirmary at Leeds in the eleven years 1936–46. During this time 7057 necropsies were performed, and in 227 (3·2%) of these some form of spontaneous cerebral hæmorrhage was found to be the main cause of death. In only 205 cases was there adequate information for the purposes of this paper, but apart from this no form of selection was used:

Site of hæmorrhage	*No. of cases*	*Cases suitable for analysis*
Cerebral hemispheres	103 ..	92
Basal ganglia	47 ..	43
Brain stem	36 ..	32
Intracranial aneurysm	33 ..	30
Cerebellum	8 ..	8
	227	205

It has long been recognised that hæmorrhage may follow cerebral thrombosis after a period of a week or more, and in such cases it appears to result from an alteration in the nutrition of an arterial wall in relation to the area of softening. In this paper such hæmorrhages have been designated secondary, whereas for those in which no antecedent thrombosis appears to have been present the term primary is used.

FINDINGS

The details are set out in the accompanying table, but certain features require special comment.

Cerebral Hemispheres.—This site accounted for 45% of all cases, but no significant differences of survival time were found for different sites within the hemispheres. No patient with primary hæmorrhage who

COMMENT

Every effort must be made, when treating infants with gastro-enteritis, to exclude parenteral infection —e.g., mastoiditis. It should *be remembered that, though* for clinical purposes streptomycin is not absorbed from the gut, about 5% does enter the blood-stream, and this amount may be sufficient to render pathogens remote from the gut streptomycin-resistant, especially where there is a coincident urinary infection. We have demonstrated in one case a urinary level of streptomycin sufficient to render the infecting coliform organism grossly resistant. In such cases it might be wise to combine oral with intramuscular *administration.*

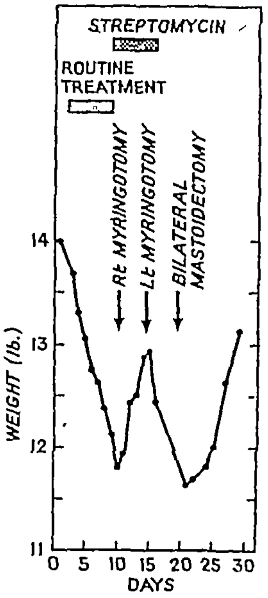

Fig. 11—Weight changes in case 18 (group C), not responding to routine treatment and given streptomycin by mouth. Bilateral mastoiditis was also present.

This investigation was started with the intention of treating gastro-enteritis associated with *P. vulgaris* in the stools, but it was found that cases with stools not containing this organism responded equally well. This experience agrees with that of Pulaski and Seeley (1948), who include among their non-tuberculous cases treated with streptomycin thirteen infants with epidemic diarrhœa of unknown ætiology. These infants were dehydrated and in shock, and they received 0·1 g. of streptomycin per lb. of body-weight daily, incorporated in their feeds, together with fluid and protein replacement. It was considered that streptomycin was the determining factor in saving at least four of the ten survivors.

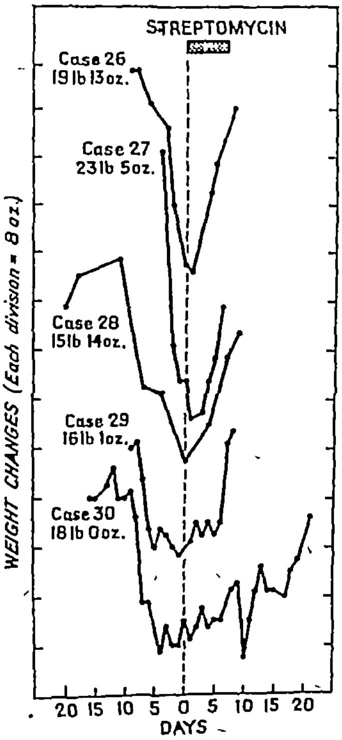

Fig. 12—Weight changes in 6 patients (group C) aged 6 months or more, not responding to routine treatment and given streptomycin by mouth.

Leisti (1947) gives an account of forty-six infants with gastro-enteritis whose stool cultures were negative; thirty-eight were full-term babies who developed gastro-enteritis when aged from 1 to 9½ months. A high proportion had blood in the stools (eight or 21%), in the vomits (seven or 18%), or in *both* (three or 8%), and of these eighteen cases twelve had been ill for less than 7 days. Streptomycin was given intramuscularly in doses of 10,000 or 20,000 *units eight times a day,* the total dosage varying from 120,000 to 8,300,000 units. Eight infants died, one did not respond to streptomycin but recovered, and two relapsed, one of whom responded to further streptomycin. The remaining eight infants were premature and developed gastro-enteritis when between 6 days and 8 weeks old. Six of these received intra*muscular streptomycin 5000* units eight times a day (total dose, minimum 80,000 units, maximum 160,000 units), and two were given 5000 units of streptomycin by mouth eight times a day (total dosages *110,000* units and *140,000* units respectively). All responded but three relapsed including one who improved with further streptomycin. Leisti concluded that the use of streptomycin is advantageous in diarrhœa of infants, and that in severe cases it often leads to a rapid recovery and a steady weight gain.

Most likely, however, there are types of infective gastro-enteritis of infants which will not respond to streptomycin given by mouth, and among these will probably be those of virus origin.

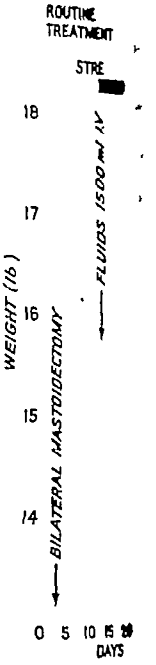

Fig. 13—Weight cha case 25 (group C responding to treatment and tomycin after mastoidectomy.

GAINS IN WEIGHT OF STREPTOMYCIN-TREATED PATIENTS AND OF CONTROLS

(P. ARMITAGE)

In groups A and B, where it was possible to observe the progress of several other cases of gastro in the same outbreaks as those from wh streptomycin-treated cases were drawn, the weight gain from the lowest weight to the *weight reached before illness in* streptomycin cases and in controls have been compared.

The trials of streptomycin in these two were not strictly controlled, since cases were not at random or alternately to the treated and groups. Since, however, the cases which wer streptomycin were chosen as being the more we *shall err in the right direction* in testing there is a significant improvement in the rate of in weight in the treated groups. There was no difference between the mean maximum weights before illness in the treated and control groups outbreak.

In each of the two series the streptomycin group showed not only a higher *mean rate* but al greater variation about the mean than the Since the usual statistical test for the difference the means of two groups is of rather doubtful when there is a considerable difference betwe variations within the groups, it was thought ad to transform the criterion to the logarithm of the *increase in weight. This transformation* tends to this sort of discrepancy. For convenience in prese each logarithm was increased by unity, and th variable has been denoted by x.

In group A (four streptomycin-treated cas twenty-three controls) the following data were ob

Mean value of x for treated group = 1·152.
Mean value of x for controls = 0·773.
Mean square (or variance) for treated group = 0·01
Mean square (or variance) for controls = 0·03011.

The mean squares are obtained by summing the of deviations from the mean of each group, divi one less than the number of observations in the o far as the weight of the heart post mortem is of as an indication of hypertension during life, s no striking association between heightened blood-re and cerebral hæmorrhage, save in the one small mentioned above.

fact that as many as 10% of fatal cases of cerebral rhage may not show free blood in the subarachnoid does not appear to be generally appreciated.

ther point is the clear-cut difference between y and secondary cerebral hæmorrhage as defined ; this would obviously be of some significance substantial series of cases of cerebral throm-were submitted to treatment with systemic gulants.

SUMMARY

clinical and necropsy records of 205 unselected of cerebral and cerebellar hæmorrhage, including ranial aneurysm, in patients dying in hospital, examined to determine the average duration of ter the onset of symptoms.

shortest time before death took place was two and over 80% of patients were dead within y-four hours.

morrhage into the brain stem and massive rupture intracranial aneurysm were associated with the st survival period, while hæmorrhage into the llum had the longest.

re was no evidence that cardiac hypertrophy was ally frequent save in cases of subarachnoid rrhage due to ruptured aneurysm in persons over ars of age.

ETERMINATION OF HÆMOGLOBIN

PRECISION OF COLORIMETRIC METHODS

. King M. Gilchrist I. D. P. Wootton

National Physical Laboratory, Teddington

. Macfarlane H. M. Jope J. R. P. O'Brien
Radcliffe Infirmary, Oxford

J. M. Peterson D. H. Strangeways
University of Wales, Cardiff

HE reliability of different colorimetric methods of mating hæmoglobin has been examined by Macfarlane al. (1948). Most of these methods were in common lical use. Included in this survey were early models a "grey-wedge photometer" which showed consider-e promise and has since been developed.* A prelimi-y account of its construction has already been blished by King (1947), and it is hoped to provide e details in a later communication. In a similar estigation to be described here, the reliability of urate instruments for measuring light absorption been compared, the grey-wedge photometer being luded. Several derivatives of hæmoglobin have been ted with the object of finding the most suitable for lical and laboratory use.

Blood samples from 11 male and 10 female normal lts have been examined in these experiments. Hæmo-bin determinations by means of iron analyses, oxygen pacities, and carbon-monoxide capacities were carried t on all the bloods. With these values as a standard of reference, various hæmoglobin derivatives were tested in the most precise instruments available, and the results compared with those obtained with the grey-wedge photometer.

APPARATUS

VISUAL INSTRUMENTS

Duboscq Colorimeter used as Photometer.—The instrument used was a Leitz two-stage compensating colorimeter illuminated with a mercury-discharge lamp. A grey screen (density 1·0) was inserted on one side of the instrument and the solution on the other. The field was viewed through an Ilford mercury green (807) filter, and several readings were taken with the screen first on the left side and then on the right side of the instrument, the solution depth being adjusted until a match was obtained. In this way the instrument was used as a photometer as described by King et al. (1937). The illumination was almost monochromatic, and the viewing conditions were considered the best obtainable.

Autenrieth Wedge Colorimeter.—The models used were manufactured by Hellige, of Freiburg, and were used with those procedures for which a standard solution can be made. Hollow glass wedges were filled for each set of experiments with the standard solutions and sealed off. The test solution was contained in a 1 cm. glass cell.

Autenrieth Colorimeter as Photometer.—The Autenrieth colorimeter is readily adapted for use as a grey-wedge photometer by the substitution of a straight neutral grey wedge for the hollow glass wedge. Grey wedges of the appropriate size were made by Messrs. Ilford with an optical density range of 0–1·2 D. A light filter (Ilford mercury green or spectrum green) was placed in the eye-piece. The instrument was similar in design and operation to the annular grey-wedge photometer described below.

N.P.L. Colour Comparator.—The instrument, which was used to determine the strengths of the carboxyhæmoglobin solutions on the Haldane scale, is essentially the same as that described by Donaldson et al. (1943). Light from a single lamp is reflected by two white screens along two paths, in one of which is the specimen tube which can be interchanged with the B. S. Haldane standard tube; in the comparison path is a movable hollow wedge filled with carboxyhæmoglobin. The two beams are then viewed in a Lummer-Brodhun photometric field of about 15° angular subtense at the eye. Brightness variation in the comparison field is obtained by rotating one of the white screens. In operation the wedge is moved until there is a colour match first with the standard and then with the specimen which takes its place. From the wedge settings and gradient the concentration of the specimen is obtained as a percentage of the standard. Since some blood samples are slightly browner than the B.S. standard tubes, a movable pale-green wedge is provided on the comparison side to compensate for the abnormality and enable an accurate colour match to be made.

Grey-wedge Photometer.—Two beams of light pass through a diffusing screen and a monochromatic light filter; in this case an Ilford mercury green (807) filter was used. The beams then traverse symmetrical paths through the photometer to illuminate adjacent optical fields viewed with an eye-piece. One beam passes through, and is strongly absorbed by, the coloured solution contained in a 1 cm. glass cell; the other beam passes through a segment of the annular grey wedge. Both optical fields are therefore illuminated with green light, and a brightness match can be obtained by rotating the wedge and so altering the segment of the wedge in the beam. The "photometric end-point" or match may be approached from either side—i.e., from darker to lighter as well as from lighter to darker—and by rotating the grey wedge back and forth over the "end-point" an accurate match can be obtained. During matching the photometer is held squarely in front of a brightly illuminated window or a strong electric light. The circular grey wedge (0–1·2 D) is mounted in a metal holder whose circumference is marked in divisions.

PHOTO-ELECTRIC INSTRUMENTS

N.P.L. Spectrophotometer.—Spectral absorptions were determined on the spectrophotometer at the National Physical Laboratory. The main features of the instrument are as follows. (1) A double monochromator system: the second spectroscope serves as a stray light filter to improve the spectral purity of the emergent monochromatic light. (2) A potassium vacuum-emission photo-cell with valve amplifier is used as detector. The potential drop across a high grid leak is

---

t is expected that this instrument will soon be available commercially.

ANALYSIS OF 205 CASES OF FATAL CEREBRAL HÆMORRHAGE IN PATIENTS WHO DIED IN HOSPITAL

Site of hæmorrhage	No. of cases	Sex		Age (years)		Survival		No. of cases in which heart weighed over 12 oz.		No. in
		M.	F.	Range	Average	Range	Average	M.	F.

Cerebellum	8	*5*	*3*	*52–76*	*61*	*8–90 hr.*	*46 hr.*	*2*	*0*	
Total ..	205	124	81	21–83	55	—	—	59	24	

died in hospital survived longer than four days, and the total number of cases (65) is sufficient to make this finding probably significant. In the secondary group no death occurred before the seventh day after clinical thrombosis. Thus between primary and secondary cases there is as striking a difference in the time of death as there is in the underlying pathology.

Basal Ganglia.—In this site the main factor influencing prognosis is whether or not rupture into a ventricle takes place, a point that is made by Newbill (1940). In the 6 cases in which this did not happen the duration of survival averaged fifty-four hours, whereas the remainder are left with an average of fifteen hours.

Brain Stem.—Many examples of minor degrees of hæmorrhage in this site were noted in association with the larger and presumably earlier lesions seen in the hemispheres or the basal ganglia; but these are not included in this group. There are two examples of hæmorrhage into the brain stem without rupture into the subarachnoid space, and in these the duration of survival was sixty-two and fifty-four hours; if these are excluded, the average for the group falls to eleven hours, the least time of survival of all.

Intracranial Aneurysm.—This is the only form of cerebral hæmorrhage that has received much attention in the recent literature, and it is included in this paper because clinically, and occasionally at necropsy, it is *impossible to differentiate it with certainty. Some* aneurysms are indeed intracerebral in their site of rupture (Richardson and Hyland 1941), and in this series *it is possible that some of the cases in younger subjects* in which hæmorrhage into a hemisphere was found in the absence of cardiovascular disease may really belong to this group. There were 6 such patients under the age of 35, but in none of them is there any evidence of special search for an aneurysm having been made. The age range within the group is not quite so wide as in most published series, but Garland (1932) found a range of 11–80 years in a series of 32 cerebral aneurysms culled from the records of the same hospital at an earlier date; the average age of his patients is much the same as here—48 years as against 46 years. The difference in average age between this group and the cases of fatal hæmorrhage from other sites is not statistically significant.

In 16 of the 30 cases in this group the age was 45 or over, and it is a striking fact that in no less than 15 of these the heart weighed 12 oz. (340 g.) or more. Forbus (1930) has drawn attention to the importance of hypertension as the cause of the rupture *in many of these* cases of so-called developmental or "congenital" aneurysms of cerebral vessels, and the finding present series support his contention.

Cerebellum.—This is not a common site for and with one exception of eight hours all the lived more than twenty-four hours. The cases is too small for conclusions to be drawn.

Weight of Heart.—This has been noted at *every necropsy; it is the only available* which to assess the importance of hypertens causal factor, for in very few cases is the bloo *known before the cerebral catastrophe, and* value of any reading is open to doubt owing raised intracranial pressure which usually follow generally accepted that the upper limit for the of the heart is about 11 oz. (312 g.), and this as the criterion of normal, though it is admi a variable, sometimes considerable, amount of weighed with the heart at routine examinations. the figures were examined on this basis, in 83 of 205 cases the heart weighed 12 oz. or more. according to sex there were 59 (48%) of 124 24 (30%) of 81 females. The only hæmorrhage in there was a striking association with increased weight was in the small group *already* patients aged 45 or more who died from rupture intracranial aneurysm, of whom 15 out of 16 this association.

Blood in the cerebrospinal fluid is a sign which is for in the differentiation of cerebral hæmorrhage thrombosis, yet in this series of 205 undoubted cerebral hæmorrhage there were 20 (10%) in which blood was found in the subarachnoid space at necro In 3 *cases rupture into a lateral ventricle* had taken but the presence of clot in the iter or in the for of Munro had prevented the further escape of the The other cases in this subgroup all tended towards longer survival period as shown in the table, and cli they had been regarded as thromboses.

DISCUSSION

Rather more than 80% of patients with cer *hæmorrhage of primary type* dying in hospital d within twenty-four hours of the onset. Massive of an aneurysm and hæmorrhage into the brain are associated with the shortest average duratio survival, whereas hæmorrhage into the cerebellum the longest; in no instance did death take place in than two hours in the 205 cases. This justifies *impression of clinicians and pathologists* that cer hæmorrhage is rarely a cause of sudden death.

luring the morning. The carboxyhæmoglobin, cyanin, and cyanmethæmoglobin colours were read later the afternoon.

visual instruments were read by several observers, umber varying from 2 to 10 (tables II and IV). To the effects of fatigue as much as possible, the us *instruments and colours* (*subject to the condition* oned above) were taken in random order. As a e, each observer read each colour in each instru-5 times, and in the case of the Duboscq colorimeter observer made 5 readings with the test solution on de and 5 with it on the other. Thus 20–50 separate tions were available for calculating the mean g of any colour in any visual instrument.

RESULTS

ase-line" *Results.*—The hæmoglobin concentra-of the various blood samples, derived from the s of the iron and gasometric analyses, are termed e-lines." These figures are considered the most mental estimates available of the hæmoglobin ntrations and are used therefore as standards st which the precision of the instrumental results be assessed. Tables I and III give the base-line s for the male and female blood series, each value the mean of duplicate and sometimes triplicate yses. In general the results calculated from oxygen carbon-monoxide capacities are 2–3% lower than e derived from iron analysis, though preliminary ction raises the carbon-monoxide capacity until it lmost equivalent to the latter. This discrepancy is ussed by King et al. (1948).

nstrumental Results.—One object of these experiments to determine which of the colorimetric hæmoglobin hods would reflect most accurately the precision e-line analyses. The reliability of any colour, however, ffected by many instrumental factors, and it was efore necessary to test each hæmoglobin derivative he several instruments. The scatter of individual dings in various instruments has already been reported cfarlane et al. 1948), and information on this is not narily sought. Of more interest was the "true ding" of the instrument, which in the case of photo-tric instruments is the actual reading obtained. For ual instruments the mean of the 20–50 readings ained by the several observers was considered the ue reading."

he data obtained, then, consisted, for each derivative asured in any instrument, in a series of "true readings" responding in each case to the accurate hæmoglobin erminations by the base-line methods. The quotients obtained by dividing the "true reading" by the corresponding hæmoglobin concentration were, with an accurate instrument, substantially constant, and the degree of constancy furnished a measure of the reliability of the instrumental "true readings." At first each of the different base-line methods was used to obtain such a series of quotients, but it very soon became apparent that the quotients obtained by using the results of the iron analyses were significantly lower, and varied less, than those derived from the gasometric methods. For this reason it is thought that iron analysis furnishes a more accurate base-line method than does any other available method, and all results presented here are calculated from quotients which have as denominator the hæmoglobin concentration obtained by iron analysis.

Each series of quotients was reduced to standard form by calculating first its standard deviation and then the Pearson coefficient of variation, defined as the standard deviation (σ) expressed as a percentage of the mean (M) —i.e., C.V. $=100\sigma/M$ (tables II and IV).

Quotients were similarly formed on the results of the gasometric base-line methods, and the coefficients of variation so obtained are also given. They enable a

measured on a potentiometer to give the amount of light on the photo-cell. (3) Light from a battery-operated car headlamp is focused on the entrance slit. The output of the lamp remains constant to within 0·05%.

Photo-electric Colorimeters.—The King (1942) single photo-cell instrument was equipped with an optical glass cell of 1 cm. depth, a 4 mm. Chance OGR I glass light-filter, and a Tinsley 4500 H galvanometer. A Hilger Spekker absorptiometer was used with Ilford spectrum yellow-green light filters. These instruments were used at the Postgraduate Medical School of London.

OTHER APPARATUS

Spectrographic Instrument.—In one series of experiments spectral curves were obtained at Oxford with the Hilger medium quartz spectrograph.

Gasometric Apparatus.—The standard Van Slyke and Neill (1924) manometric apparatus was used at the Postgraduate Medical School of London, at Cardiff, and at Oxford, and, in addition, Warburg manometers were used at the P Medical School of London.

Glassware.—Standard volumetric flasks of "A" q were used. The calibrations were checked by weighing and filled with distilled water. Ostwald-Folin p calibrated by weighing "to contain" were used fo measurement of all blood samples; errors in the deli such a viscous fluid were eliminated by rinsing the into the receiver with distilled water. For other o standardised delivery pipettes were used.

METHODS

All specimens were taken by one of us (R. G. M.) Radcliffe Infirmary, Oxford. A tourniquet was to the upper arm, a 16-gauge needle inserted i antecubital vein, the tourniquet removed, and allowed to pass through a short rubber tube into a containing mixed potassium and ammonium o The donors were healthy males and females aged about 300 ml. was taken from each subject. thorough mixing, and with precautions to avoid errors, the blood was divided into three parts and in screw-cap bottles, whose caps, lined with 'Cello were tightly screwed on. Bottles were then di by mail to London and Cardiff and were received first delivery next morning. Analyses in these lab were therefore begun about twenty-four hours after blood had been taken; those at Oxford were com on the day the blood was taken.

"*Base-line*" *Methods.*—At the Postgraduate Medical of London, titanous-chloride titrations of the iron con residues after dry ashing were carried out according analytical procedure of Delory (1943) as modified by al. (1948). At Oxford Klumpp's (1934) method was u gasometric methods described by Peters and Van Sly were followed in all samples. All these methods, toget the Warburg-manometer technique of oxygen capacit been fully discussed by King et al. (1948). In all c results of these "base-line" analytical methods w verted into hæmoglobin concentrations by means of (1894) factors—i.e., hæmoglobin contains 0·334% iro of hæmoglobin = 1·34 ml. of oxygen or of carbon mon

Colorimetric Hæmoglobin Methods.—Oxyhæmoglob oxyhæmoglobin, cyanmethæmoglobin, acid hæmatin, hæmatin, and cyanhæmatin were prepared ex described by King and Gilchrist (1947) and by M et al. (1948).

Time of Reading Colours.—The oxyhæmoglobin, hæmatin, and alkaline-hæmatin colours are preferal at a definite time after their formation; they were th

EXPLAINED THROMBOSIS OF THE INTERNAL CAROTID ARTERY

H. R. I. WOLFE
M.B. Lond., F.R.C.S.
ASSISTANT, SURGICAL UNIT, WELSH NATIONAL SCHOOL OF MEDICINE, ROYAL INFIRMARY, CARDIFF

e following case the sudden onset of coarse neuro- signs followed by eighteen months' gradual ement suggested cerebral vascular disease, and graphy demonstrated thrombosis of the internal artery.

CASE-RECORD

hly built woman, aged 26, was admitted on Jan. 16. omplaining of difficulty in speaking. There was relevant in her family history. Since the age of 1 year been treated for a concomitant squint of the left eye. a routine examination for this condition in 1939 it n noted that, unknown to the patient, the eye had blind. Apart from this she had been well until 1945.

ug. 13, 1945, while serving in the A.T.S., she had got ng perfectly well. After dressing she tried to move a r, felt a sudden weakness in the right arm, and fell ground, without losing consciousness but unable to She was taken to the casualty reception centre and bed. On that day she tried to write but was unable the words. At that time she began to have sharp g left temporal headache, radiating to the frontal There was anorexia but no nausea or vomiting. On d day she suddenly developed weakness in the right

e end of September, some six weeks after the original , she began to write and read, though she had difficulty ng words when writing and in understanding words ading. Power gradually returned to the right arm and d by mid-October she was allowed up, and fourteen er she could walk half a mile without distress. Though turned to her right arm, she was unable to perform er-to-thumb test accurately with her right hand. By d of October she had lost the distressing headaches had come on intermittently during the previous two s. Improvement continued until December, 1945, he was invalided from the Service.

r this there was gradual improvement in the aphasia. ll had difficulty in speaking owing to an inability to find and remember them. Reading was also difficult, since ld not understand some of the words in the text, but ability was much less than previously and gradually sed. She was not troubled with further headaches. re was only slight residual disability of the arm and e right hand "felt clumsy" but she could do household , knit, sew, and write. If she walked much, her right foot came clumsy.

ination.—She was alert and coöperative and tended the light of her illness. There was a moderate aphasia, difficulty in finding words. She had difficulty also in standing what was said. She could read and spell words the text, but some of them she could not understand. re was slight nystagmus, greater on looking to the right. ight incoördination of the right arm, the finger-to-nose test performed rather clumsily. Her gait was steady. here was no sensory disturbance or loss of power in the . The cranial nerves were normal. The tendon-jerks present but perhaps a little more brisk on the right the abdominal reflexes were present in all quadrants. he plantar response was flexor on both sides.

nd movements at 3 ft. and light could only be appreciated e left eye. The visual field in the right eye was full. The of both eyes appeared normal, and no abnormality of optic disc or of the vessels of the left eye was detected. e heart was normal on both physical and electrocardio- ic examination. Blood-pressure 116/70 mm. Hg. Pulsa- was normal in the radial, anterior tibial, posterior tibial, dorsalis pedis arteries. There was no evidence of temporal itis. There was no pulmonary lesion. The blood rombin-time was 90% of normal, and the Wassermann ion negative.

mbar puncture produced clear watery fluid under a ure of 125 mm. of water. The rise and fall of C.S.F. pressure on jugular compression was rather sluggish. C.S.F. normal on examination. Kahn test negative.

Radiography showed general thickening of the bones of the skull, particularly the inner table of the vault. The mastoid air cells and the sphenoidal and ethmoidal sinuses were normal. In the rest of the skeleton nothing abnormal was found, nor was there any calcification of blood-vessels.

Arteriography (Jan. 25, 1947).—Exposure of the left carotid vessels for arteriography showed feeble pulsation in the external carotid, but the internal carotid was pulseless. Arteriography revealed an occlusion of the internal carotid about 2 cm. above the bifurcation of the common carotid artery (see figure). Periarterial stripping was performed at the bifurcation.

Electro-encephalography (Oct. 16, 1947) confirmed the site of the brain lesion.

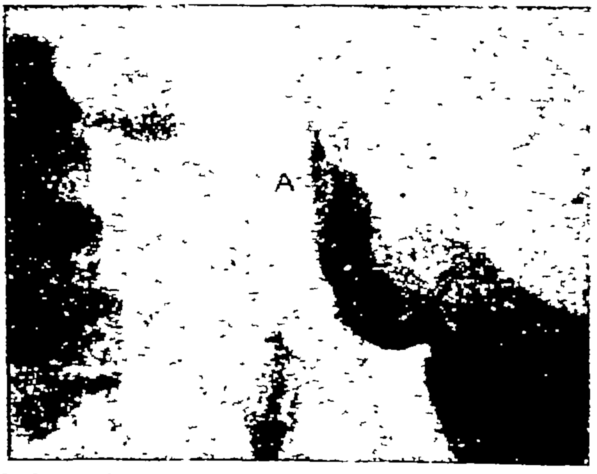
Progress.—Convalescence was uneventful. Eight months later, on Oct. 27, 1947, she was readmitted to hospital because she had become dull and apathetic, lacked initiative, and was careless of her appearance and bodily hygiene. Pneumo-encephalography showed much cerebral atrophy and asymmetry of the ventricles.

Operation (Nov. 8, 1947).—Under general anæsthesia a left superior cervical ganglionectomy was performed, and the left external and internal carotid arteries were divided between ligatures 1 cm. above and below the bifurcation of the common carotid artery. The diameter of the internal carotid artery was much reduced, and its peripheral portion appeared to be obliterated, its lumen being occluded by a firm white thrombus extending downwards into the common carotid artery and upwards into the external carotid artery for a few millimetres, partially occluding the lumina of both vessels.

Microscopical Findings.—A little proximal to the bifurcation of the common carotid artery organised thrombus filled most of the original lumen, leaving irregular channels containing fluid blood. The thrombus was attached to the intima over half the circumference of the vessel, with several gaps where fluid blood was in contact with the intima. The media was practically normal, with no obvious degenerative or inflammatory change. Close to the bifurcation of the common carotid artery the state of the external carotid artery resembled that of the common carotid artery, but the internal carotid artery had been completely thrombosed and recanalised, after which a further thrombosis had developed in one of the newly formed lumina. The media of this vessel was thin, appeared degenerate, and was penetrated by small vessels running from the perivascular region to the organised thrombus. There was only a slight inflammatory cellular infiltration in the vessel and surrounding tissues.

Further distally the external carotid artery had progressively less of its lumen occupied by the organised thrombus, whereas the internal carotid artery was almost completely obliterated throughout the length examined.

Progress.—Convalescence was uneventful, but up to Sept. 6, 1948, there had been no demonstrable improvement in the patient since operation.



Angiogram showing occlusion of left internal carotid artery: A, cone-shaped termination of opaque 'Thorotrast' column just below atlas.

comparison to be made between the reliability of gasometric and colorimetric methods of estimating hæmoglobin.

Spectrophotometric Results.—For all the samples of blood (11 male and 10 female) the spectral absorptions of each of the six hæmoglobin derivatives were measured on the N.P.L. spectrophotometer. Values were determined at each 10 mμ throughout the visible spectrum.

The coefficients of variation (tables II and IV) are based on absorption measurements at 540 and 560 mμ; detailed information on the spectral data will be reported elsewhere.

DISCUSSION

This investigation has been based on the principle used in previous work on the reliability of methods for determining hæmoglobin (Macfarlane 1945, King et al. 1944, Macfarlane et al. 1948). This is the comparison of the results obtained by several observers using the less precise routine methods with the results obtained on the same blood sample by the most precise methods available. In the present investigation some of the instruments tested were more elaborate and precise than the average routine determination of hæmoglobin requires; but their comparison with simpler procedures is instructive. For this reason the performance of two spectrophotometers, two photo-electric colorimeters, and standard visual colorimeters and photometers has been investigated in comparison with that of the small neutral grey-wedge type of photometer, which has been developed experimentally during the course of the work on hæmoglobin estimation. This last instrument, after several structural modifications, now appears to be in a form suitable for routine use and manufacture.

The validity of the base-line determinations has already been discussed in previous papers in this series, and iron analysis has again been taken as the standard of reference. It appears to provide the point of least variation from the other quantitative determinations which, in this instance, have involved several different derivatives of hæmoglobin. It will be seen that hæmoglobin mass as determined by iron analysis is very close to that derived by carbon-monoxide capacity after preliminary reduction, whereas oxygen-capacity estimations give consistently lower figures. It is reasonable to accept these two higher estimations as being the nearer to the true figure.

The variations of the results by the colorimetric and photometric methods have been calculated from the standard deviation of the ratios of observers' results to iron content of the blood samples used. Several points of interest arise regarding these estimates of reliability. The first is that, despite its simplicity, the neutral grey-wedge photometer gives results that are generally as good as those of the more elaborate and expensive instruments! Secondly, in these experiments the single-cell photo-electric colorimeter has proved more reliable than the more complicated two-celled absorptiometer. Thirdly, as regards the suitability of the various hæmoglobin derivatives for visual colorimetric or photometric estimation, it appears that oxyhæmoglobin and cyanhæmatin give the least variable results on the whole. Acid and alkaline hæmatin are inferior, though alkaline hæmatin gives good results when used in photo-electric instruments. In view of the disadvantage of cyanhæmatin for general routine use, because of the cyanide used, oxyhæmoglobin appears to us to be the derivative of choice for the neutral grey-wedge photometer. It not only gives good results but also is the simplest pigment to prepare.

Estimates of the reliability of the different methods, when used in different laboratories, are fairly consistent, apart from an occasional discrepancy. There seems, however, to be a curious difference between the results on blood samples from males as opposed to females. The latter show a greater over-all variation, particularly with certain pigments, such as acid hæmatin. N
for this can at present be given.

The constancy of the relationship between
concentration and instrumental reading in the
the grey-wedge photometer indicates the p
of calibrating the scale of the instrument
hæmoglobin values may be directly obtained.
information on this point is in course of pr

It seems, then, that the grey-wedge ph
capable of accurate results when enough
obtained by several observers. To be satisfac
it is essential that the scatter between the
different observers, each taking only a few
should be small. This point was covered by
et al. (1948), who showed that this scatter was,
when using oxyhæmoglobin, smaller than that
the hæmoglobinometers tested. It is therefore
that the grey-wedge photometer should provide
venient clinical hæmoglobinometer of
accuracy.

SUMMARY

The results of experiments to test the
precise colorimetric methods of estimating h
are described.

Samples of normal blood from 11 male and 10
adults were used.

Tests of six hæmoglobin derivatives ind
oxyhæmoglobin and cyanhæmatin give the most
results. The performance of a new neutral
photometer of simple construction compares
ably with that of standard photo-electric and
instruments.

EXPLAINED THROMBOSIS OF THE INTERNAL CAROTID ARTERY

H. R. I. WOLFE
M.B. Lond., F.R.C.S.
ASSISTANT, SURGICAL UNIT, WELSH NATIONAL SCHOOL OF MEDICINE, ROYAL INFIRMARY, CARDIFF

e following case the sudden onset of coarse neuro- signs followed by eighteen months' gradual ement suggested cerebral vascular disease, and graphy demonstrated thrombosis of the internal artery.

CASE-RECORD

ghtly built woman, aged 26, was admitted on Jan. 16. omplaining of difficulty in speaking. There was relevant in her family history. Since the age of 1 year been treated for a concomitant squint of the left eye. a routine examination for this condition in 1939 it en noted that, unknown to the patient, the eye had blind. Apart from this she had been well until , 1945.

ug. 13, 1945, while serving in the A.T.S., she had got ng perfectly well. After dressing she tried to move a ox, felt a sudden weakness in the right arm, and fell ground, without losing consciousness but unable to She was taken to the casualty reception centre and bed. On that day she tried to write but was unable the words. At that time she began to have sharp g left temporal headache, radiating to the frontal There was anorexia but no nausea or vomiting. On rd day she suddenly developed weakness in the right

he end of September, some six weeks after the original d, she began to write and read, though she had difficulty ing words when writing and in understanding words eading. Power gradually returned to the right arm and d by mid-October she was allowed up, and fourteen ter she could walk half a mile without distress. Though returned to her right arm, she was unable to perform er-to-thumb test accurately with her right hand. By d of October she had lost the distressing headaches had come on intermittently during the previous two s. Improvement continued until December, 1945, she was invalided from the Service.

r this there was gradual improvement in the aphasia. ill had difficulty in speaking owing to an inability to find and remember them. Reading was also difficult, since uld not understand some of the words in the text, but sability was much less than previously and gradually ved. She was not troubled with further headaches. here was only slight residual disability of the arm and he right hand "felt clumsy" but she could do household , knit, sew, and write. If she walked much, her right foot became clumsy.

mination.—She was alert and coöperative and tended the light of her illness. There was a moderate aphasia, difficulty in finding words. She had difficulty also in standing what was said. She could read and spell words the text, but some of them she could not understand. re was slight nystagmus, greater on looking to the right. slight incoördination of the right arm, the finger-to-nose being performed rather clumsily. Her gait was steady. here was no sensory disturbance or loss of power in the . The cranial nerves were normal. The tendon-jerks present but perhaps a little more brisk on the right the abdominal reflexes were present in all quadrants. he plantar response was flexor on both sides. nd movements at 3 ft. and light could only be appreciated e left eye. The visual field in the right eye was full. The i of both eyes appeared normal, and no abnormality of optic disc or of the vessels of the left eye was detected e heart was normal on both physical and electrocardio- hic examination. Blood-pressure 116/70 mm. Hg. Pulsa- was normal in the radial, anterior tibial, posterior tibial, dorsalis pedis arteries. There was no evidence of temporal itis. There was no pulmonary lesion. The blood hrombin-time was 90% of normal, and the Wassermann tion negative.

umbar puncture produced clear watery fluid under a sure of 125 mm. of water. The rise and fall of C.S.F. pressure on jugular compression was rather sluggish. C.S.F. normal on examination. Kahn test negative.

Radiography showed general thickening of the bones of the skull, particularly the inner table of the vault. The mastoid air cells and the sphenoidal and ethmoidal sinuses were normal. In the rest of the skeleton nothing abnormal was found, nor was there any calcification of blood-vessels.

Arteriography (Jan. 25, 1947).—Exposure of the left carotid vessels for arteriography showed feeble pulsation in the external carotid, but the internal carotid was pulseless. Arteriography revealed an occlusion of the internal carotid about 2 cm. above the bifurcation of the common carotid artery (see figure). Periarterial stripping was performed at the bifurcation.

Electro-encephalography (Oct. 16, 1947) confirmed the site of the brain lesion.

Progress.—Convalescence was uneventful. Eight months later, on Oct. 27, 1947, she was readmitted to hospital because she had become dull and apathetic, lacked initiative, and was careless of her appearance and bodily hygiene. Pneumo-encephalography showed much cerebral atrophy and asymmetry of the ventricles.

Operation (Nov. 8, 1947).—Under general anæsthesia a left superior cervical ganglionectomy was performed, and the left external and internal carotid arteries were divided between ligatures 1 cm. above and below the bifurcation of the common carotid artery. The diameter of the internal carotid artery was much reduced, and its peripheral portion appeared to be obliterated, its lumen being occluded by a firm white thrombus extending downwards into the common carotid artery and upwards into the external carotid artery for a few millimetres, partially occluding the lumina of both vessels.

Microscopical Findings.—A little proximal to the bifurcation of the common carotid artery organised thrombus filled most of the original lumen, leaving irregular channels containing fluid blood. The thrombus was attached to the intima over half the circumference of the vessel, with several gaps where fluid blood was in contact with the intima. The media was practically normal, with no obvious degenerative or inflammatory change. Close to the bifurcation of the common carotid artery the state of the external carotid artery resembled that of the common carotid artery, but the internal carotid artery had been completely thrombosed and recanalised, after which a further thrombosis had developed in one of the newly formed lumina. The media of this vessel was thin, appeared degenerate, and was penetrated by small vessels running from the perivascular region to the organised thrombus. There was only a slight inflammatory cellular infiltration in the vessel and surrounding tissues.

Further distally the external carotid artery had progressively less of its lumen occupied by the organised thrombus, whereas the internal carotid artery was almost completely obliterated throughout the length examined.

Progress.—Convalescence was uneventful, but up to Sept. 9, 1948, there had been no demonstrable improvement in the patient since operation.

INTESTINAL OBSTRUCTION FROM FIBROUS STRICTURE

FOLLOWING STRANGULATED HERNIA

P. KONSTAM
F.R.C.S.E.
LATE RESIDENT SURGICAL OFFICER, CRUMPSALL HOSPITAL, MANCHESTER

Barry described three cases of this rare condition and fully reviewed published cases.[1] Two more cases came under my care within three weeks of each other.

Case 1.—A man, aged 69, was admitted to hospital on Sept. 22, 1945, with the history that a large right inguinal hernia, which he had had for many years and for which he wore a truss, had become strangulated and been reduced by taxis by his own doctor before admission. A large tender right inguinal hernia was found, not completely reducible, and with no sign of strangulation. The patient was admitted for observation. Pain and vomiting recurred, and operation was undertaken.

First Operation (Oct. 2).—A coil of ileum 4 in. long was found fixed in the hernial sac; there were well-developed truss adhesions. No definite evidence was found of interference with the blood-supply to the gut which was therefore returned to the abdominal cavity. The hernia was repaired.

Progress.—On Oct. 8 the patient began to vomit and complain of lower abdominal pain. There was no distension of the abdomen, and flatus was passed. On Oct. 13 there was severe colicky central abdominal pain and the patient vomited several times. His bowels had not been open for two days. There was some central distension of the abdomen. The condition settled with the passage of Ryle's tube and with gastric suction. The patient was discharged on Oct. 10. He was readmitted on Oct. 30 with a history of pain across the abdomen and in the back for ten days and constipation for two days. There had been no vomiting. His tongue was furred, and his temperature and pulse-rate were normal. A step-ladder pattern of small gut coils was visible. There was much distension of the central abdomen, with tinkling peristaltic sounds. Subacute intestinal obstruction in the region of the terminal ileum was diagnosed.

Second Operation.—The ileum was much distended and contained gas and fluid. A segment just proximal to the ileocæcal junction was narrowed and indurated, with two large glands in its mesentery. The terminal section of the ileum was normal. An ileo-transverse colostomy was made.

The patient was discharged on Nov. 23 after an uneventful recovery. Seen as an outpatient on Jan. 15, 1946, he said he had had diarrhœa for six weeks after discharge but was now well.

Case 2.—A man, aged 60, was admitted to hospital on Oct. 10, 1945, with eight hours' history of colicky abdominal pain. He had vomited much brown material. His bowels had been open the day before. He had had a right femoral hernia for eight years. On admission his pulse and temperature were normal, and his tongue dry. His abdomen was a little distended, with loud tinkling noises on auscultation.

First Operation.—The femoral sac was opened and found to contain 6 in. of strangulated but viable small gut, some omentum, and some plum-coloured fluid. The contents of the sac were reduced and the hernia repaired.

Progress.—On Oct. 24 the patient complained of colicky central abdominal pain and vomited some bile. His abdomen was not distended. On Nov. 6 there were further attacks of intestinal colic, with loose motions. An anteroposterior radiogram of the abdomen did not justify a diagnosis of obstruction. On Nov. 7 the patient's temperature was 100°F and his abdomen soft. Stools showed no occult blood or pathogenic organisms. On Nov. 15 there was well-marked abdominal distension, with pain more severe. Audible peristalsis suggested obstruction of small gut.

Second Operation.—The ileum about 5 in. from the ileocæcal valve was indurated and narrow, like a rubber tube. The gut above the obstruction was much distended. The constricted segment was 2 in. long and $^3/_4$ in. in diameter, and tapered towards the ileocæcal valve. A constriction ring was still present. The related mesentery showed several

DISCUSSION

The history is characterised by the sudden onset of aphasia and weakness of the right arm followed three days later by weakness of the right leg and a subsequent gradual but incomplete recovery. Eighteen months after the original incident there was slight mental deterioration, aphasia, and remnants of a right-sided hemiplegia. Arteriography showed thrombosis of the left internal carotid artery. Subsequently a segment of the common carotid, external carotid, and internal carotid arteries on the left side was excised. The internal carotid artery appeared to be completely occluded by a thrombus extending a short distance into the common and external carotid arteries, which were partially occluded. Microscopically the walls of the common and external carotid arteries were not obviously diseased, but there was degeneration in the media of the internal carotid artery and a slight inflammatory cellular infiltration of that vessel and its perivascular tissue. The structure of the thrombus in the internal carotid artery showed that complete thrombosis had been followed by recanalisation and subsequent further thrombosis. The neurological signs suggest that extension of the clot distally took place on the third day, arterial spasm being unlikely in view of this latent period. Almost complete recovery from the hemiplegia suggests recanalisation.

The demonstrable vascular occlusion was presumably responsible for the neurological symptoms, but the cause of the thrombosis is more obscure. There was no evidence of injury whereby the vessel might have been damaged. Minute injuries due to muscular exertion, or abnormally developed fascial bands, were thought by some a possible cause of "idiopathic" thrombosis in the femoral and popliteal arteries of young men in the Services during the war. The bifurcation of the common carotid artery in the present case was abnormally high and may have rendered the internal carotid artery liable to such an injury and subsequent thrombosis. This hypothesis is only speculative, since the evidence for holding normal anatomical structures responsible for "idiopathic" thrombosis is not strong.

There was no evidence of an inflammatory process or of a tumour in either the bone or the soft tissues in relation to the artery, and nothing to indicate syphilis. Embolism is unlikely, since this girl had no sign of either valvular disease or myocardial damage. Repeated observations of the blood-pressure (116/70) did not show any significant fluctuations, and in the absence of either palpable or radiological evidence of arteriosclerosis there is little to support the assumption that either hypertensive arteriosclerosis or a sudden drop in blood-pressure was responsible.

Radiography of the skull showed a general thickening, particularly of the inner table of the vault. One reported case of thrombosis of the internal carotid artery subsequently developed Christian-Schüller's disease (Andrell 1943). Though the radiological change in the skull might be interpreted as that following spontaneous healing of a xanthomatous lesion, this diagnosis appears unlikely, since there was neither a previous history pointing to skeletal xanthomatosis nor other evidence of this condition.

It is unfortunate that there is no record of an examination of the C.S.F. when this young woman was first taken ill, for it is just possible that a "berry" aneurysm of the circle of Willis was responsible for the thrombosis. In the necropsy records of the Cardiff Royal Infirmary there is an account of a fatal subarachnoid hæmorrhage due to a "berry" aneurysm at the termination of the internal carotid; the lumen of the vessel was partially occluded by an extension of clot from the aneurysmal sac. This is the only one of 35 cases in which partial occlusion was reported, and I have been unable to find a published report of a case in which complete was found.

Thrombo-angiitis obliterans, a progressive lesion of the arteries with secondary th generalised disease of the blood-vessels and may any organ. Thrombosis of one internal ca in association with cerebral thrombo-angiiti observed (Sorgo 1939, Antoni 1941, Sunder 1941, Andrell 1943, Davies and Perret 1947). thrombo-angiitis tends to involve the smaller the hemisphere, and the affected cortex shows softening, glial scar tissue, and normal cortex encephalography in the present case showed due to atrophy. Though cerebral thrombo thought to be responsible for the thrombosis in in the absence of clinical signs of more vascular disease or a systematic examination vascular system which could only be done at the diagnosis cannot be regarded as established.

Previously Recorded Cases

Numerous cases of thrombosis of the ca have been published. Thrombosis of the c artery is rare, and bilateral thrombosis Frøvig (1946), who reported a case, found 11 similar cases. Most of the reports concern of the internal carotid artery. I have found 32 cases (Lohr 1936, Moniz 1937, Shimidzu et al. 1938, Riechert 1938, Siegert 1938, Andrell 1943) in which thrombosis was arteriographically. In these cases and in the the age and sex of the patients and the side the lesion occurred were as follows:

Age (decade) ..	3rd	4th	5th	6th	7th
No. of patients ..	1	6	4	11	10

Males 26; females 7.
Left side 23: right side 10.

Arteriosclerosis is thought by Andrell (1 responsible for the thrombosis in most cases. from 6 of the 32 cases previously described was pathologically. In 1 fatal case, Antoni (1 changes in the cerebral vessels due to thro In 5 a segment of the occluded vessel showed sclerosis had caused the thrombosis in 3, and angiitis in 2. In the remaining 17 cases was diagnosed in 7, no cause could be found vascular pathology in 7, 1 was thought to thrombo-angiitis, 1 was associated with sy was followed by Christian-Schüller's disease.

Diagnosis

The diagnosis is difficult. The duration of and their transient character in the early stage cerebral vascular disease. Pneumo-encepha provide evidence of cerebral atrophy. Precise requires arteriography.

In a little over half the cases the disease chronically progressive course, and an characterised by transient cerebral symptoms recognised. Premonitory attacks of headache most constant. The headache, localised to the the lesion, transient, and of short duration, periodically for years before the manifestation symptoms. Occasionally it is associated with disturbances or with neurasthenic symptoms. paresis, hemiparæsthesia, speech difficulties, sient blindness have been reported. These which develop in attacks of short duration and rapidly, are followed after months or years by severe attacks, the last at times being apoplectic. the cases here described, this stage may be at the first sign of the disease be the acute onset neurological symptoms, the commonest being he involving chiefly the arm. Initially this may be

CLINICAL APPLICATION

rvations seem important in several clinical which renal cortical ischæmia is probably ing pathogenic factor—namely, essential , pre-eclampsia, traumatic anuria, and For some time we have been interested in relationship between toxæmia of pregnancy hypertension, for the best results of splanch- or hypertension seem to be obtained in se disease originates in pre-eclampsia. The romes of pre-eclampsia and of eclampsia t of malignant hypertension so closely that to believe that they have not a common al cortical ischæmia, and that it is possibly factor which makes malignant hypertension hereas pre-eclampsia and eclampsia improve mination of the pregnancy. Further, it has that renin can be detected in the blood of pre-eclampsia and in those with eclampsia those with malignant hypertension. We ned our attention to patients with pre- was found that by blocking both splanchnic procaine the blood-pressure could always a normal level. The blood-pressures before anchnic block in five consecutive patients re:

Blood-pressure (mm. Hg)

0/105	150/95	190/100	160/90	195/115
0/75	100/60	130/70	110/70	170/100

was made to render the splanchnic block t alcohol was unsuitable because of the acing it sufficiently accurately and because ly followed by severe intercostal neuritis, tocaine ' was unsuitable because it diffused hen proctocaine, rendered radio-opaque by f a little iodised oil, was injected at the h and 12th dorsal vertebræ, it tracked as lumbar vertebra in forty-eight hours.

tried T.E.A.B. and found that an intra- of 0·5 g. usually produced a well-marked ary fall in blood-pressure (see figure). nsion was usually, though not invariably, ut 15 min. We then used T.E.A.B. by injection to obtain a prolonged effect, hourly for twenty-four hours followed urly for twenty-four hours. The initial ppointing. Only four cases have so far t in the last case the blood-pressure fell y-four hours after the last injection and about seven days. Probably, therefore, E.A.B. must be given for a much longer desired effect.

COMMENTS

e the answer to the problem of treatment related syndromes in which the renal narily at fault. Repeated large doses of trial in the prevention and treatment as concealed accidental hæmorrhage, d possibly blackwater fever, all of which nied by oliguria due to renal cortical

terrupted through unforeseen circum- usly incomplete, but it is hoped that y give the method a wider trial.

SUMMARY

eta et al.[1] on the presence of two alter- athways through the kidney has been tition of their experiments.

tetraethylammonium bromide on the has been studied in rabbits, and an intramuscular dose of 0·2 ml. of a 10% solution per kg of body-weight has been shown to prevent cortica ischæmia.

Intramuscular doses of 1 g. six-hourly for twenty-fou hours, followed by 1 g. three-hourly for twenty-fou hours, caused the blood-pressure to return to norma for seven days in 1 out of 4 cases of pre-eclampsia.

It is suggested that a longer period of this treatmen may have the desired effect in a greater proportion of cases.

I wish to thank my colleagues Prof. T. N. A. Jeffcoate, Mr. St. George Wilson, and others for allowing me to study patients with pre-eclampsia admitted under their care. We are grateful to Pharmaceutical Specialities (May and Baker) Ltd. for the tetraethylammonium bromide used in the animal experiments.

Reviews of Books

Surgery of Abdominal Hernia

GEORGE B. MAIR, M.D., F.R.F.P.S., F.R.C.S.E., surgeon, Law Junction Hospital, Lanarkshire. London: E. Arnold. 1948. Pp. 408. 25*s*.

THIS book really consists of two parts—a monograph on the use of whole-skin grafts in hernia repair, and, round this, a general treatise on hernia. The first, which conveys the author's views and experience, is the best; the remainder is painstaking and impersonal, and (as always when a writer is editing the views of others rather than stating his own) is overloaded with quotations from obscure surgeons supporting bizarre theories. Lytle's masterly description of the internal ring, which agrees with those of Astley Cooper and Hesselbach, is ignored, and we find in its place a circular sphincter of muscle which was apparently seen by someone in 1929.

Mr. Mair's use of the purely Scottish word "outwith" goes with a clear style and forthright manner, and his account of his own work with whole skin will interest most surgeons. A record of 140 indirect herniæ operated on by this method with only 1 recurrence after a year, and of 40 direct herniæ similarly treated with no recurrence after three years, is one of which anyone might be proud. But while the author's advocacy and his results will persuade many surgeons to try his technique, its ultimate survival will depend on the results that others get. It is clear that the graft is eventually converted into, or replaced by, a firm sheet of fibrous tissue, but only after a battle lasting six months in which fibroblasts, foamy cells, and giant cells struggle over dead epidermis, hair fragments, desquamated elastic fibres, clumps of bacteria, and small abscesses. Clinically these struggles seem to be indicated by a local reaction greater and more prolonged than usual.

The book usefully fills a place. It will be consulted by those who want a clear account of the whole-skin graft method of repair, and by those who seek information and references in relation to rare or atypical herniæ.

Disorders of Sex and Reproduction

A. P. PILLAY, M.B. London: H. K. Lewis. 1948. Pp. 299. 18*s*.

IN former days sexual difficulties and impaired fertility were generally neglected by doctors, mainly because they were not lethal; and now their treatment has passed into the hands of the gynæcologist, the urologist, the endocrinologist, and the psychologist. This has the disadvantage that patients have to be referred from one doctor to another during the course of their treatment, and Dr. Pillay argues that it would be better for them to be under the care of a single specialist in "sexology." He has devoted himself for many years to the diagnosis and treatment of sexual and reproductive disorders in both sexes, and this book is the fruit of his varied professional experience. It gives a balanced view of forms of illness which often cause great mental distress, even though they are not the cause of serious strands of fibrous tissue, and there were several large hard mesenteric glands, one of which was taken for biopsy. The affected bowel was short-circuited by an ileo-ileostomy. The gland showed changes due to pyogenic infection, and when cultured yielded a pure growth of *Staph. pyogenes*.

The patient made an uninterrupted recovery.

COMMENTS

These patients were 69 and 60 years old. In one case signs of obstruction developed 18 days after reduction of a strangulated right inguinal hernia, and in the other between 14 and 35 days after operative reduction of a strangulated right femoral hernia. In one case necrosis of the mucosa gave rise to diarrhœa 21 days after strangulation; the diarrhœa in the other case was possibly a result of ileo-transverse colostomy. Growth of *Staph. pyogenes* from a mesenteric gland in the second case suggests that damage to the mucosa allowed the organisms to penetrate to the deeper tissues of the bowel.

Neither case showed intestinal hæmorrhage. The diagnosis of Crohn's disease was ruled out by the histories. Both patients did well after a simple short circuit of the affected part of the ileum.

I am indebted to Dr. W. Ramsay, medical superintendent of Crumpsall Hospital, Manchester, for permission to publish these cases, and to Dr. G. Stewart Smith for the pathological report.

Preliminary Communication

TETRAETHYLAMM[illegible]ONIUM BROMIDE IN RENAL CORTICA[illegible]L ISCHÆMIA

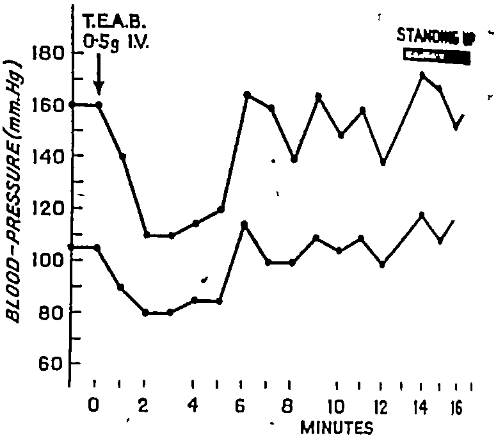
TRUETA et al.[1] have presented [illegible] new picture of the circulating pathways in the kidney [illegible] us clinical states. importance in the pathogenesis of vario[illegible] d studied the We have confirmed their observations [illegible] the renal effect of tetraethylammonium bromide [illegible] application circulation, especially as regards its possibl[illegible] pregnancy to the prevention and treatment of toxæmia [illegible] and other conditions.

Experiments were first made to inject th[illegible] o normal renal circulation. Rabbits of about 2 kg. bod[illegible]-weight which is were injected with indian ink by the technique w[illegible] ked- advocated by Trueta et al. and very satisfactory n[illegible] as eye appearances were produced. The technique i[illegible] follows:

> The mesenteric vessels are ligated, and a hypodermic nee[illegible] is inserted into the abdominal aorta just above the bifurcat[illegible] and directed against the blood-stream. The aorta is next tie[illegible] round the needle. 'Mandarin' indian ink diluted 1 in 3 is injected so that the head of the injected mass is kept just above the origin of the renal arteries. This point can be found by observing the colour of the left suprarenal gland, which becomes and remains black while the ink is kept at the correct level, but rapidly becomes pale if there is insufficient ink in the aorta.

The normal kidney injected in this way rapidly becomes uniformly black after 3 or 4 ml. of ink has been injected. The renal pedicle is next clamped, and the kidney removed and fixed in formalin for twelve hours, after which it is sectioned and photographed. The cortex of the normal kidney appears uniformly black to the naked eye.

In other rabbits faradic stimulation was applied to the left splanchnic nerve for 10 min. The surface of the kidney became pale and, when 3–4 ml. of indian ink had been injected, appeared irregularly red and black, showing that some areas of the cortex were ischæmic. If 20 ml. of ink was injected over a longer period, the cortex became uniformly black, and a cut section showed ink distributed throughout cortex and medulla, suggesting



Blood-pressure of patient with pre-eclampsia treated with T.E.A.B.

that the vascular spasm could be overcome by pressure in the renal artery.

Effect of Crushing a Limb

Observations were next made to confirm the [illegible] crushing the limb. The rabbit was [illegible] intravenous pentobarbitone sodium supplemented [illegible] open ether as required. A wire tourniquet was [illegible] to the left hind limb sufficiently tight to [illegible] circulation and crush the muscles without [illegible] them. The tourniquet was left on for $4^1/_2$–5 h[illegible] which the same injection technique was used. [illegible] found, as Trueta et al. noted, that the k[illegible] injected unevenly, the left being more patchy [illegible] right.

Effect of Splanchnic Paralysis

Trueta et al. state that the vascular [illegible] kidney depends on the integrity of the sp[illegible] and that after section of the nerve the [illegible] shunt cannot be produced. No attempt was [illegible] confirm this particular observation directly, [illegible] were interested in a more rapid method of [illegible] renal circulation—by the use of the rap[illegible] sympathetic paralytic drug tetraethyl[illegible] mide (T.E.A.B.). This was given in 10% [illegible] intramuscular injection, the dose being 0·2 ml [illegible] of body-weight.

The rabbit was anæsthetised as before, [illegible] muscular T.E.A.B. was given. A tourniquet [illegible] applied as before for $4^1/_2$ hours, and indian [illegible] injected. The injection pattern was completely [illegible] nd identical with that of a normal kidney. Th[illegible] ent was repeated in 6 rabbits with similar [illegible] ggesting that an adequate dose of T.E.A.B., [illegible] application of the effective stimulus, was as [illegible] splanchnic section in preventing the renal [illegible] mia.

as [illegible] clinical practice, however, such co[illegible] isch[illegible] ly to arise, and it seemed more important In [illegible] whether T.E.A.B. would be as effective if gi[illegible] unlik[illegible] ter the effective stimulus. The experi[illegible] mine [illegible] re repeated, and an intramuscular inj[illegible] time [illegible] was given in different rabbits one, two, therefo[illegible] ter the application of the tourniquet. T.E.A.B. [illegible] n which only one or two hours had hours [illegible] the stimulus and the injection of T.E.A.[illegible] rabbits [illegible] ulatory pattern was normal, whereas between [illegible] which a longer period had elapsed [illegible] renal cir[illegible] rtical ischæmia. It therefore seemed rabbits in[illegible] the development of renal cortical isch[illegible] usually co[illegible] E.A.B. after the application of the to prevent [illegible] despite the persistence of that st[illegible] injecting T.E[illegible] interval was not too long. stimulus, an[illegible] provided the i[illegible]

two modes of adaptation to tension may be
ve cultural responses to a situation that
dividual has to deal with in his own develop-
Mental growth results from a complex of
ing impulses of love and hate and our picture
lves and the social world in which we live is
at first permeated with images of fantastically good and fantastically bad people. It is commonly reckoned an advance towards maturity when we can recognise the good-and-bad in ourselves as well as the good-and-bad in those around us: we achieve an accommodating, not over-demanding, attitude to ourselves and to others In some societies this flexible and tolerant way of social life is transferred to the community, and to those who are its symbol and executive The State is not divine, nor yet is it abhorrent

In the individual's relation to the State there is again a contrast between the democratic and the totalitarian societies; for the former have evolved a sociopolitical device by which the people, without disloyalty or disruption, can express hostility to authority. In England and the United States interest in politics is split into two. One portion is reserved for the Crown (in America for the Constitution and the Supreme Court), and discontent, however active, does not disturb it: the other portion is focused on the Cabinet, which discontent can remove from office without upsetting the fundamental relation to the central authority But totalitarian nations have no comparable device **Hitler** made himself a god to his people, and had no cabinet worth attacking. The leading one-party State of the present time, Soviet Russia, has likewise exploited the notion of an omnipotent ruler, and provides hardly any means by which people can legitimately express discontent with the policy of their government on major issues. Instead, the hostility that the rulers might incur by their shortcomings is often diverted to some external agency—a custom that menaces international harmony, by producing uncontrollable suspiciousness and a paranoid attitude to neighbours.

Another and different factor which makes the present situation dangerous is that the acquisition of great military force excites latent ambition which would otherwise lie dormant. We cannot ignore the fact that the invention and virtual monopoly of atomic weapons puts a strain on American statesmanship, and that possession of these instruments places excessive power in the hands of a minority of citizens. A nation which is by tradition democratic is thus labouring under some temptation to behave like an ambitious oligarchy—a temptation to which in the past we ourselves have sometimes succumbed, but to which at the moment we are not exposed

England today stands between two great Powers who do not understand each other, and who might each be irritated into supposing that war would bring advantage to the world If in such risky circumstances we are to justify our reputation for political common sense we should perhaps pause before committing ourselves emotionally to either side; for in so doing we should lose any remaining chance of serving as mediators. Moreover, we might run a risk of denying a principle for which our ancestors fought and died, and towards which we strive in our slow growth as individuals. Nothing is harder to remember in a time of crisis, but at no time is it more necessary to recall that it takes all sorts to make

es which follow birth, is unevenly distributed,
ust consider that our responsibilities remain
illed."

is last chapter Professor Ryle touches on a practice
as troubled many conscientious doctors—that of
ious surgical operation undertaken on a wide range
ients before its value has been assessed by adequate
logical study and by thorough follow-up of early
Operations are devised, and then studied by trial
rror, by men of limited experience as well as
ed ones. He asks whether, for example, vagotomy
soligation have yet been justified either by animal
man experiment, and whether the partial and
rary successes and the complete failures have
udicially studied and reported, as a counterweight
complete successes. He believes the answer to
questions, and others equally searching, is either
' or "We do not know." Experiments, usually
and safe, carried out on patients who are willing
eers and understand the purpose of the investiga-
re, he thinks, entirely permissible, especially if
im to decide whether a given line of treatment will
ve a patient's condition; they are harder to
if they are designed merely to advance theoretical
edge and if the patient must be persuaded to agree
n. He might have added something about the type
estigation which carries a risk, whether to life or
: cystoscopy in the partially paralysed bladder is
s a fair example. Who knows what the risks are
y? The patient does not even know that there
y, and is given no chance of deciding whether he
to take them; the surgeon usually has an
ession" about the risks in general, and an
ion" about the risks for this patient; he also has
therapy at the back of his mind as a saving measure
gs go wrong. Yet the risks, even of temporary
fort, should always be carefully weighed against
formation which the method is expected to yield.
or Ryle would like every research clinician con-
ting an experiment to ask himself three questions;
hese might well serve, too, for those undertaking
e examinations: "Would I accept that this
ment or investigation should be carried out in
r circumstances on a member of my own family?
ould I accept that it should be carried out without
ll coöperation and consent? In the presence of
iable risk, do the possible results for science or
ine help to justify the risk?"

may also ask, he suggests, that new operations
ng a danger to life or subsequent health should not
dertaken by men of limited experience before their
has been proved by others; and that methods of
-up should be much stricter, wherever possible
ding a personal interview by a trained medical
worker.

PATIENTS' READING

E International Federation of Library Associations
hospital subcommittee which met during the recent
rence of the federation in London. The discussions
led differences in various countries in the attitude
medical profession and the extent to which reading
ld to have a therapeutic value. In Denmark the
e, which is entirely staffed by professional librarians,
little if any account of the condition of the patient.
reat Britain the general attitude of doctors, with
notable exceptions, is to leave the patient an
ely free choice, though in tuberculosis sanatoria
mental hospitals there is a definite movement to
reading as a contribution to treatment. In
ce there is a good deal of difference of opinion among
cal men. In Belgium the service is admirably
nised by the Belgian Red Cross under the direction
rofessional librarians, who are encouraged to take
urse in social science. The Red Cross librarians read all the books before circulating them, and have a code to denote any risks which may attach to issuing them to particular types of patients. In some hospitals in the United States the conception of the therapeutic value of reading has reached the stage of prescribing books like medicine, and requiring a report from the librarian on the effect on the patient.

At the meetings it proved possible to obtain general agreement to a resolution that, while preserving the liberty of the individual patient, the librarian must appreciate the possible effect of the book upon him. Also approved were resolutions that public librarians should have special training for hospital work, that the voluntary workers who distribute the books should have some training, and that the attention of doctors and all concerned with hospitals be directed to the value of this work.

MECHANICAL ARTIFICIAL RESPIRATION

THE "iron lung," introduced by Drinker in the United States in 1929, and its modification the Both respirator which Lord Nuffield generously provided for British hospitals, are still saving lives which would otherwise inevitably be lost from respiratory failure. The uses found for the Both respirator have ranged from the treatment of overdosage with paraldehyde,[1] hitherto almost invariably fatal, to the prevention of post-operative atelectasis.[2] Persistent apnœa is no longer regarded as necessarily deadly in hospitals possessing a Both respirator. In other circumstances the first-aid teaching, whether in medical school, factory, or police force, is to apply manual artificial respiration by the method of Schäfer or Silvester, or by the even simpler and more efficient[3] rocking method of Eve, until the patient recovers or is transported to a hospital, which in England is never very far. In America, where Lord Nuffield's benefaction has not been emulated, and where distances are much greater, a Society for the Prevention of Asphyxial Death has for many years been stimulating interest in this subject. With their vigorous affection for up-to-date mechanical devices, the Americans have been attracted to automatic means of artificial respiration, and breathing machines have been widely distributed for use in the mine, by the canal bank, or even in the gas suicide's bedroom. Some have even been adapted to supply the airman with oxygen under intermittent positive pressure at high altitudes. There has therefore been a constant search for cheaper, lighter, and more compact apparatus which is yet sufficiently robust. Commercial competition has stimulated a variety of designs, all working on the principle of direct inflation of the lungs by oxygen under pressure. Controversy has raged for years over the relative merits of the different patterns. Motley and his colleagues[4] show that in practice all are fairly satisfactory, and that all will oxygenate the patient better than the traditional manual methods. The apparatus gradually builds up the pressure under the face mask during the inspiratory phase and allows it to fall rapidly to zero (i.e., atmospheric) at the start of expiration, so mimicking natural unimpeded respiration. Surprisingly the "suck-and-blow" machines, which inflate the chest during inspiration and also suck air from it in expiration, proved to have no advantages over the more usual patterns which only inflate. It appears that the "suck" is but poorly transmitted to the interior of the thorax.

The possibility that mechanical artificial respiration may have side-effects on the heart has hitherto been discussed largely on the basis of clinical impression. Now Motley and his co-workers have shown how very

FINANCIAL ARRANGEMENTS

financial arrangements are the same in principle hout the Union; only the payments vary. All its receive stipends which are sufficient to maintain and pay the very low fees. Outstanding students receive extra stipends, and the best get Stalin c prizes, which take the form of a large incremen stipends. The stipends increase from year to ye cease if the student twice fails to pass his examina

The payment of fees by the students is intende inculcate a sense of responsibility and ability to man their own budgets. Thus, the students receive stipen of 220–700 roubles a month. They have dining-rooms and dormitories, recreational and games facilities, and many other amenities, all of which are free, except for a daily charge of about 3·5 roubles for three meals a day.

Fees amount to 300–450 roubles a year, but seldom more than 60% of students pay the full fees, privileges being given to special groups.

THE MEDICAL CURRICULUM

At present the course lasts six years but it may be extended to seven in the near future.

First Year.—The subjects are Marxism-Leninism (a form of training in logic and philosophy), Latin. English, physics, biology, and parasitology; a start is made on anatomy, histology, physiology, embryology, analytical chemistry, and biochemistry.

Second Year.—Students continue with English, anatomy, histology, embryology, the chemistries, and physiology. At the end of this year is held the "half" State examination—an intermediate examination which weeds out the unsuitable students. The following subjects must all be passed at the same time, failure in one involving failure in all: (1) human anatomy, (2) histology and embryology, (3) physiology, and (4) biological chemistry. Permission to "sit" again may be obtained and students are often placed in other careers.

Third Year.—Here the "broad specialisation" begins to influence the subjects taught. The students start the study of microbiology (bacteriology), pathological physiology, pharmacology, pathological anatomy, diagnostics and "private" pathology and therapy, and general surgery. He has commenced clinical attendances in his second year (some even start in the first) and will continue these until the end of the course. At the end of this term there is an examination (not a "State" examination) and the student does his first "physician's practicum." He repeats this in the summer of the fourth year and in the fifth summer will do his "physician's subordinator"—a form of internship. These clinical periods involve about seven hours a day for at least three months.

In the *fourth year* the students really begin their specia training as general practitioners, pædiatricians, sanitary physicians, &c. There is an examination at the end of this year.

The *fifth year* sees the completion of the apprenticeship and many of the smaller subjects, such as venereal diseases, pædiatrics, tuberculosis, infectious diseases, ophthalmology, radiology, &c. The range of these is complete; there are no omissions.

The *sixth year* is more intensely clinical, finishes off the special subjects, and completes the intensive clinical studies.

The number of hours given to each subject is shown in the accompanying table.

FINAL STATE EXAMINATION

The final examination (known as the "full" State examination) always has nine subjects, every one of which must be passed at the same sitting.

A. *General Medical Faculty ("broad specialisation")*

1. Human anatomy
2. Pathological anatomy
3. Pathological physiology
4. Internal diseases (=medicine)
5. Surgical diseases
6. Obstetrics and gynæcology
7. Infectious diseases
8. Children's diseases
9. Hygiene

dependent is the cardiac output on the variations in intrathoracic pressure during the respiratory cycle. Any deviation from the normal in this respect is followed by a parallel alteration in the heart's output, though not always in the same direction. Thus a raised pressure throughout the respiratory cycle produces a proportional fall in the cardiac output. Provided the mask pressure drops rapidly to atmospheric at the end of inspiration, and provided inspiration and expiration are of equal duration, no cardiac embarrassment need be feared when using mechanical substitutes for normal respiration.

The wide distribution of small mechanical respirators may give the layman a new and perhaps undesirable conception of the treatment of asphyxia. This danger has been emphasised repeatedly by Paluel Flagg and Yandell Henderson in America. A few years ago, Flagg wrote[5]:

> "If a child inhales a peanut or a pin, he is hustled off to the hospital and receives every advantage of the bronchoscopic clinic. Should he be so unfortunate as to inhale something larger, a marble or a chunk of meat, he is no longer in need of medical help. Everything will be solved if *the suck and blow apparatus used last week in the* stevedore down the street can be secured."

Henderson[6] called the suck-and-blow type of machine "a back-step towards the death of thousands." In this country, until it is certain that the expense of mechanical respirators would be justified in lives saved, we cannot do better than train our doctors and first-aiders to use the simpler methods of treating asphyxiated people.

FOR SMOOTHER RUNNING

STORIES of patients annoyed and frustrated by the way they are received at hospitals are too common to be ignored. The chilly welcome, the unguided search for the ward, the long hours of waiting in the outpatient department, and the obligation to repeat the same basic facts to every hospital officer who asks, are familiar vexations to the people who use, and now own, the hospitals. Such bad hospital manners are often the outcome of an archaic system of administration in a hospital which has outgrown its floor-space and is scarcely able to deal with the work it is equipped to do. Trouble is caused by out-of-date filing systems, puzzling methods of registration and record-keeping, lack of an appointments system, and other remediable defects. King Edward's Hospital Fund for London, in the hope of clearing the way for better customs, recently held a short course for administrative officers, to enable them to study the admission systems in a number of hospitals which have lately been reviewing the subject. The course was supervised by Mr. S. W. Barnes, house-governor of King's College Hospital, and he and the members of the course have now drawn up a report of their findings.[7]

Of 8 hospitals visited, 5 made appointments for new and old patients. The arrangements work well if they have the support of the doctors on the staff; but as this, unfortunately, is not always ungrudging, the task of arranging the appointments system must be placed in the charge of "an enthusiastic and tactful officer who will study their individual needs and gain their active coöperation." It is better, Mr. Barnes and his colleagues decided, to make the system compulsory, no outpatients being seen without an appointment unless they are referred from the casualty department as urgent cases. This helps to make patients and their family doctors appointment-minded. A patient who arrives without a doctor's letter, saying he feels ill, is seen by the casualty officer and, if his condition is urgent, is referred to a consultant. The writers of the report believe an appointments system, besides saving the patient time and trouble, simplifies the work of the hospital in several ways: it saves space, eases the work of the records staff, shows which clinics are overcrowded, and ensures a steady flow of patients to the ancillary departments. The list of patients due to attend can be used by the appointments office when checking misplaced notes, and makes the counting of outpatient attendances easier. The writers recommend that there should be one central appointments office to deal with the attendances at all clinics and departments. Events can then be made to dovetail, the patient polishing off his visits to various clinics on a single day, and special reports on his condition being completed in time for his next consultation.

The medical staff, wanting to reserve cases for teaching, sometimes insist that they cannot do this until they have read the doctors' letters. At King's College Hospital the appointments staff, who have been told what types of case to reserve, open all letters and make appointments accordingly. In the case of old patients, consultants mark the folders of the cases they need for teaching. The medical committee should be told when clinics are booked up a long way ahead, since it may be possible to arrange an extra clinic; and a margin of time is usually left, when appointments are made, so that urgent cases can be fitted in.

Some long-needed strictures on the appearance of outpatient departments should be appreciated by patients. *To ask a sick person to sit for hours on a* wooden bench in a cheerless flagged hall, watching the fat neck of the man in front, or listening to the wheezing *of a neighbour or the fretful crying of a tired bored child* is as good a way of turning his uneasiness to anxiety and his anxiety to downright fear, as could well be devised. The report urges some overdue reforms—light-painted walls, coloured comfortable chairs, odd tables and plenty of papers and magazines—something more like a doctor's waiting-room and less like an approach to a morgue.

Again, "the patients' opinion of the hospital will be largely formed by the way they are treated at registration"; hence registration clerks need to be "tactful, kind and patient, with a pleasing personality." Some good detailed advice on the management of waiting-lists should also promote the comfort of patients. They should be given some idea of the time they will have to wait, warned to tell their own doctor if they get worse, and given a new forecast by letter "at least every three months." This last, somewhat ironic, proposal shows what a wounded snake our waiting-lists have become.

Every hospital, the writers consider, should have a medical records committee to define policy and keep the wayward doctors to it. A standard design of case-sheet is advocated within the hospital, but not between hospitals, since this would damp initiative and stultify progress. Hospitals must go on testing new methods. Details of cabinets, filing systems, and staffing of the *records department need close study. In silent comment* on human fallibility, the writers advise that the records office should be locked after hours, and that those seeking notes at such times should be made to sign for the key.

The *Times* reports that the World Health Organisation is arranging a conference of government representatives from war-devastated European countries. At the World Health Assembly Soviet Russia supported a large programme of supplies for these countries, and it was decided that Europe should have a temporary office "for the liquidation of war damage" in the field of health. The conference, which will meet at Geneva on Nov. 15, will consider the nature of the services required.

DR. ROBERT CRUICKSHANK has been appointed to the chair of bacteriology at St. Mary's Hospital as from Jan. 1, 1949.

MEDICAL EDUCATION IN THE UKRAINE

W. P. Forrest
L.R.C.P.E., D.P.H.
TE CHIEF MEDICAL OFFICER, UNRRA UKRAINIAN MISSION;
W SPECIAL ASSISTANT TO THE DIRECTOR-GENERAL, WORLD HEALTH ORGANISATION, GENEVA

In Soviet Russia all medical students are trained with view to occupying planned posts in a State health stem. For example, since children constitute about a rd of the population and their care is entirely ispensarised," it is intended that a third of all doctors duating should have some special knowledge of diatrics. A similar arrangement holds for the other nches of the medical profession, but the targets are t always reached.

The system of education and the curricula are stan- rdised throughout the U.S.S.R. In each republic all dical education is subject to supervision by the local nistry of the Care of Health, which supplies the funds d the personnel, and the Ministry of Higher Education, ich manages the institutes. These ministries are bject to supervision by the All-Union Ministries in scow. All professional examinations are All-Union aminations, so a minimal standard is maintained roughout the country, and a diploma or other qualifica- n obtained in one part of the country is valid in every ber.

CATEGORIES OF MEDICAL WORKERS

Qualified medical practitioners have received their ining in higher educational institutes and are classified follows: medical practitioners with "broad" speciali- tion; medical specialists with "narrow" specialisa- n; medical research specialists; assistants (teaching or arch); aspirants; candidates; docents; professors; tors of medical sciences; corresponding academicians; emicians.

dical Auxiliaries.—The higher institutes are respon- for the education of pharmacists, and the lower tutes for that of dentists (not stomatological cialists), feldshers and feldsheritsas, pharmacists' stants, and medical nurses.

State sanitary inspectors are educated in the higher titutes.

ENTRANCE EXAMINATIONS

A candidate for entrance to a higher institute must ve attended a ten-year school for pupils aged 7–17 nd either hold the silver or gold medal of that school or ss the entrance examination of the institute he has hosen. The choice of profession and institute is free, nd students are given every facility to meet the pro- ssors to have the curriculum and prospects explained. his is a routine procedure during the last years at the en-year school. Special privileges are accorded to war terans and children of Heroes of the Union.

All entrance examinations are held on or about the me date, and the students must surrender their birth rtificates and school diplomas on entry to the examina- ion; hence it is virtually impossible for them to sit several xaminations in the hope of passing one of them.

A candidate for entrance to a lower institute must ave attended a seven-year school and is usually required o pass an entrance examination. Lower institutes are oughly equivalent to the technical schools in industrial ducation.

FINANCIAL ARRANGEMENTS

The financial arrangements are the same in principle throughout the Union; only the payments vary. All students receive stipends which are sufficient to maintain them and pay the very low fees. Outstanding students receive extra stipends, and the best get Stalin prizes, which take the form of a large incremen stipends. The stipends increase from year to ye cease if the student twice fails to pass his examina

The payment of fees by the students is intende inculcate a sense of responsibility and ability to mana their own budgets. Thus, the students receive stipen of 220–700 roubles a month. They have dining-rooms and dormitories, recreational and games facilities, and many other amenities, all of which are free, except for a daily charge of about 3·5 roubles for three meals a day.

Fees amount to 300–450 roubles a year, but seldom more than 60% of students pay the full fees, privileges being given to special groups.

THE MEDICAL CURRICULUM

At present the course lasts six years but it may be extended to seven in the near future.

First Year.—The subjects are Marxism-Leninism (a form of training in logic and philosophy), Latin, English, physics, biology, and parasitology; a start is made on anatomy, histology, physiology, embryology, analytical chemistry, and biochemistry.

Second Year.—Students continue with English, anatomy, histology, embryology, the chemistries, and physiology. At the end of this year is held the "half" State examination—an intermediate examination which weeds out the unsuitable students. The following subjects must all be passed at the same time, failure in one involving failure in all: (1) human anatomy, (2) histology and embryology, (3) physiology, and (4) biological chemistry. Permission to "sit" again may be obtained and students are often placed in other careers.

Third Year.—Here the "broad specialisation" begins to influence the subjects taught. The students start the study of microbiology (bacteriology), pathological physiology, pharmacology, pathological anatomy, diagnostics and "private" pathology and therapy, and general surgery. He has commenced clinical attendances in his second year (some even start in the first) and will continue these until the end of the course. At the end of this term there is an examination (not a "State" examination) and the student does his first "physician's practicum." He repeats this in the summer of the fourth year and in the fifth summer will do his "physician's subordinator"—a form of internship. These clinical periods involve about seven hours a day for at least three months.

In the *fourth year* the students really begin their specia training as general practitioners, pædiatricians, sanitary physicians, &c. There is an examination at the end of this year.

The *fifth year* sees the completion of the apprenticeship and many of the smaller subjects, such as venereal diseases, pædiatrics, tuberculosis, infectious diseases, ophthalmology, radiology, &c. The range of these is complete; there are no omissions.

The *sixth year* is more intensely clinical, finishes off the special subjects, and completes the intensive clinical studies.

The number of hours given to each subject is shown in the accompanying table.

FINAL STATE EXAMINATION

The final examination (known as the "full" State examination) always has nine subjects, every one of which must be passed at the same sitting.

A. *General Medical Faculty* ("*broad specialisation*")

1. Human anatomy
2. Pathological anatomy
3. Pathological physiology
4. Internal diseases (=medicine)
5. Surgical diseases
6. Obstetrics and gynæcology
7. Infectious diseases
8. Children's diseases
9. Hygiene

B. *Pædiatric Faculty* (" *broad specialisation* ")

1 to 6 as above
7. Children's diseases
8. Children's infectious diseases
9. Hygiene

C. *Faculty of Sanitary Physicians* (" *broad specialisation* ")

1. Microbiology
2 to 5 as above
6. Epidemiology and infectious diseases
7. Environmental hygiene
8. Hygiene of " feeding "
9. Hygiene of labour (industrial medicine)

The successful student is entitled to a diploma which states that he has passed the State examination, that he has studied six years at the institute, and that he is a qualified physician with broad specialisation in whichever subject has been his specialty.

Examinations (except State examinations) are not so important as the personal file, which is kept for each student and shows every detail of his academic career. This is on the examiner's table. It is also used at the State examinations, where it usually has no more than 50% significance.

Some of the smaller institutes only graduate students of group A.

ON GRADUATION

A newly qualified doctor commands a salary of 800 roubles or more a month according to his record. Housing is guaranteed—a tremendous concession—and is free. Special rations of food and clothing are granted, and in the country the doctor receives a garden, a cow and other livestock, and special rations of fuel and other scarce commodities.

An inspector from the All-Union Ministry of the Care of Health meets the graduates and shows them the list of vacancies, from which they choose. The best students are retained by the professors for training as research-workers and teachers. The professor who has vouched for such a student must report every six months to the Uchonny Soviet—a council of research-workers. This enables a control to be kept on all such workers.

Except those taken for research or teaching, all graduates must spend their first three years where the ministry wishes to send them—i.e., they are subject to direction. Many stay on in the posts to which they were directed, after the end of the three-year period.

RESEARCH

The division of institutes into teaching and research entities, so extensively practised in all other branches of science in the U.S.S.R., has been fought by the medical profession. They have retained the more familiar mixed institutes, and are quite elated about it, since some other professions are now convinced that the medical profession was right. So these teaching institutes are 50% research, and the teaching staff divides its time equally between research and teaching. Research in this country very often involves large hospitals and much clinical work.

MEDICAL AUXILIARIES

Pharmacists and State sanitary inspectors are trained in higher institutes, and all the other medical auxiliaries in lower institutes.

Pharmacists are employees of the Ministry of the Care of Health and operate chemists shops controlled by that ministry. Supplies come from the Ministry of Medical Industry. They have a four-year course and receive diplomas.

State sanitary inspectors are in a rather different category, since the State sanitary inspection is an independent organ of the central government, responsible to the local health authorities at each level, but with power of appeal to the chief of the State sanitary inspection in the Ministry of the Care of Health in Moscow. Thus he has direct access to the Council o Ministers of the U.S.S.R. It is therefore both an operativ and a controlling organisation. It possesses the wides powers, and woe betide the wretched plant manager o even State minister of health who contravenes th sanitary laws. In practice, little friction arises, and most useful function is undoubtedly performed by thi service.

State sanitary inspectors who are always medicall qualified, have a 1–2 years' course in special institutes o sanitary science and receive a diploma. The curriculun in these courses covers all the usual aspects of sanitar science including industrial, food, meat, and environ mental hygiene, and the hygiene of public utilities. Th course and the policies are decided according to the lates medical hygienic opinion supplied by the All-Unio Ministry of Health. One of the deputy ministers o health of any republic or State is always a sanitar inspector.

The other medical auxiliaries are all educated in lowe institutes and spend some time as apprentices to experi

enced members of the same profession before taking up independent work. It is planned to have four medical auxiliaries for every one doctor.

Dentists are really dentists' assistants and always work under the supervision of stomatological specialists, who are medical practitioners whose specialty is the mouth. They have a three-year course similar to the old four-year dental courses in other countries but with more emphasis on the practical side and less on academic work. They work in stomatological clinics, children's clinics, mothers' clinics, factory polyclinics, and in rural areas.

Feldshers and Feldsheritsas.—These are mostly to be found in rural areas or where there is a population too small to support a full-time doctor—i.e., less than 1500 population. The Feldshers provide the lieutenants and sub-lieutenants of the army medical service, and usually do much the same work as would be done by highly qualified nurses in the U.S.A. and U.K. They operate feldshers' points in the country, usually one for each small group of villages or collective farms, and small sanitary points in factories too small to have a factory doctor or polyclinic. Their duties are strictly laid down, and they are always responsible to the district medical officer, who they must call in or consult for any occurrence above a given level and in all cases of infectious disease. They do the doctor's "donkey-work" in the country and provide first-aid. They are educated in lower institutes for three years. The training is again more practical than academic but is very well designed for the duties they have to perform. They receive a diploma and serve their first two years as assistants to experienced feldshers in the field, after which they manage their own unit or practice. They have a most important educational function and are the first link in the collection of medical statistics. Feldsheritsas are permitted to work in towns to be near their husbands. Over 60% of all feldshers are women.

Feldsher midwives receive a three-year course (almost exactly the same as the course for midwives in Scotland but more extended, with greater practice) in lower institutes. The feldsher midwife serves in maternity homes and hospitals in the urban areas and is in charge of the lying-in houses which must be provided by the collective farms. She manages these, looks after antenatal and postnatal care, arranges consultations, and registers all pregnancies and births. Her duties are strictly laid down, and she is responsible to the local doctor for maternal care. She carries out much educational work.

Medical Nurses.—It is to be expected, in view of the existence of feldshers and feldsher midwives, that nurses would come in rather lower down the medical scale, and such is the usual case. Nurses receive two years' training in lower institutes, including much practical work (half of the time) in hospitals and polyclinics, and receive a diploma. They are not commonly seen in the countryside, except in village hospitals, polyclinics, or ambulatories attached to the district medical headquarters. Their sphere of action is in the urban areas, where they are to be found in all medical institutions. Extensive facilities are provided for them to improve their status, especially in the field of the care of children's health, where they can become directors of orphanages, nurseries, and other institutions maintained by the health authorities for children up to the age of four. They are also to be seen in sanatoria and rest-cure establishments. All discipline of nurses is always the responsibility of the chief nurse of the institution who in turn is responsible to the director; she does not have the other administrative functions of the U.S.A. or U.K. matron. It is unusual for a nurse to be responsible to a feldscher.

Pharmacists' assistants stand to the pharmacist as dentists do to the stomatologist. They are trained for 2 or 3 years and serve in chemists' shops.

POSTGRADUATE EDUCATION

Postgraduate education has been instituted "continually to raise the qualifications of medical w of all kinds." Facilities are available for all me workers to take refresher courses arranged, in consultat. with the requisite institute, by Oblasdrav (rough equivalent to county medical administration). The worker is notified and goes for various periods of a month upwards to the institute to which he is directed. While he attends the institute he receives a stipend almost equal to his salary, and his family receives his salary. No fees are charged.

In the Ukraine there are four institutes for postgraduate studies for physicians: Kiev (the oldest), Kharkov, Odessa, and Lvov (the newest). The postgraduate work is usually, but not always, combined with specialisation to fit the practitioner for a more important post in Oblasdravotdel (county health-administration affairs).

Apart from raising the standard of proficiency of the medical practitioners and bringing their knowledge up to date, and providing further specialisation (but not making them specialists) these institutes provide one of the main channels for training medical specialists for teaching and research. This is done by providing "ordinature"—i.e., internship and training for medical specialists—and "doctoranture"—i.e., facilities for preparing an M.D. thesis. The institutes do not give degrees as doctors (or candidates); these are given only by the Academy of Sciences, which works in close coöperation with the institutes. This work usually takes 2 or 3 years. The institutes also coöperate in research work, which is always closely integrated with teaching. The various faculties of the institutes are usually in the same premises as the research units.

Registers are kept of all doctors who have passed through the institutes, and these records are available to assist any other health institution in staffing problems. The institutes advise Oblasdrav on optimum staff requirements, as regards both numbers and specialisation, and encourage Oblasdrav in raising the general standard of its employees. This is a two-way arrangement and in no case constitutes direction of one party by the other. Oblasdrav is obliged to listen to the advice of the institutes, and vice versa.

These institutes are large and are not located in one building, and several chairs are attached to each large teaching and research hospital or institute. In Kiev there are thirty-three chairs, which can prepare students for more than 33 specialties. Thus the entire range of postgraduate medical study is fully covered.

THE FINISHED PRODUCT

It is difficult for a stranger to assess the finished product, but by all pragmatic standards the graduates appear to be as well qualified as their contemporaries in other countries, and indeed better than in some. To judge by the curriculum and the calibre of the instruction, they must be better prepared than most, but the present serious shortage of specialised equipment undoubtedly nullifies some of the advantages of the very full course of instruction and practice. This will pass, however.

To judge by results, the students are very well trained indeed. Medical teachers declare that the graduate of today is vastly superior to his predecessor of even ten years ago; they proved themselves well able to do excellent work in the appalling conditions and almost total lack of modern facilities prevailing during the occupation; it is generally recognised that they did excellent work with the Red Army; and there have been no epidemics in Russia, in spite of ideal circumstances for outbreaks of infectious disease.

It is considered that other countries have something to learn from the educational methods in force here, and especially from the integration of medical education with the national requirements for medical personnel.

I am indebted to the Hon. I. F. Kononenko, formerly Minister of Care of Health for the Ukrainian S.S.R., and Dr. Lev. I. Medved, now Minister, who have accorded me every facility; Prof. S. S. Kagan, chair of organisation of health, who has been my guide, philosopher, and friend; Professor Kalchenko, director of the Kiev Postgraduate Institute; Docent Kalainichenko, director of the Kiev Medical Institute, and all the other professors, docents, and physicians who have supplied me with information.

MEDICAL PROTECTION SOCIETY

Sir Ernest Rock Carling, the president, addressing the annual general meeting of this society held in London on Sept. 29, said that it had had another successful year: the membership had steadily increased and the financial position was sound. With the coming of the National Health Service the future was uncertain; but nothing in past experience suggested that attacks on the profession by disgruntled patients would grow fewer. Government departments had a tendency to compromise, without clearing the character of the professional person attacked; and lawyers were inclined to exaggerate the alleged shortcomings of the medical man, attributing to his neglectfulness and hard-heartedness—if not actual malice—the entire effects of accident or disease. The costs of medical protection were likely to rise rather than fall; but the society faced the future with confidence and solid assets. One advantage it might gain from the National Health Service was that the doctor would have to keep good records; for in the past many a case had been prejudiced for lack of notes.

Remarking on the trouble caused by broken hollow needles, Sir Ernest said that in all cases where the society had submitted the fragments to a metallurgist a manufacturing defect had been found. He hoped for improvement of manufacture, but also reminded members that needles must not be cleaned with, or immersed in, solutions of iodine, which even in minute traces could erode and weaken them. Another source of frequent trouble lately had been fracture of the jaw during dental extractions. This was by no means always the result of bad work: it was often due to osteomyelitis, which could be properly treated only by removal of the offending teeth. Nevertheless wherever there was a possibility of osteomyelitis leading to fracture it was important to radiograph the jaw first.

Where there was some mishap the doctor or dentist was often uncertain whether he should tell the patient (or the relatives). In the vast majority of cases the patient should be informed: to give the facts never redounded to the practitioner's discredit.

The objects of the society, said Sir Ernest in conclusion, were not merely to protect medical men: having the same objects as medicine as a whole, it was concerned with prevention as well as defence, and it sought at all times to encourage correct professional behaviour.

The society's expenditure for the year 1947 averaged 23*s*. 3*d*. per member, though the subscription remained at £1. With accumulated funds standing on Dec. 31 at £112,991, the resources available for protection were £145,816, and the society is reinsured to an unlimited amount against adverse costs and damages exceeding a specified amount during any one year.

Tribute was paid at the meeting to the late Mr. G. F. Stebbing, who has been succeeded as chairman of council by Dr. G. M. Stoker. Sir Robert Hutchison spoke in warm terms of the service rendered to the society by Sir Ernest Rock Carling, who was re-elected president.

Mr. W. M. Mollison will serve again as treasurer.

Dr. A. R. French was appointed secretary of the society in place of Dr. R. W. Durand, who is going to Belfast as medical superintendent of the City Hospital.

Disabilities

14. POLIOMYELITIS

I CONTRACTED poliomyelitis two years after I ha qualified. During the first epidemic in Dublin, in Apri 1941, I developed what seemed to be a full-blow meningitis. Lumbar puncture was a great comfor Paralysis developed over two days, from the leg upwards. At its height I could just breathe unaided b concentrating hard, and chewing, swallowing, and faci expression were unaffected; otherwise I could onl move my fingers and turn my head on the pillow. Fo three days I had retention of urine and double visio In the next week there was a decided improvemen and thereafter a very slow recovery. I developed extre tenderness along the nerves and tachycardia, both which persisted for 6 months. After 4 weeks' illness, f reasons of occupation and economy, I asked to be broug home, though I was sorry to leave the fever hospit where everyone was wonderfully kind to me.

Being impatient for recovery, and encouraged by t delusion that I would soon reach it, I worked hard at m muscles from the start, despite the invariable appeal those days to "avoid overdoing it." By the 6th wee I could turn over in bed in 45 minutes, by exerting sy tematic traction on my pyjamas and sheets and leveri my pelvis sideways with my knuckles. By the 3rd mont I could travel slowly round the bed. It still took m five minutes to turn over, and I felt faint in ten minut if I sat up, despite a firm abdominal belt. I was so waste that my finger and thumb would meet round my ar from wrist to elbow and from elbow to shoulder. At months I could just manœuvre myself off my low be on to my hands and knees on the floor and back agai and at 9 months I could struggle up sideways into sitting posture, crawl short distances, and negotiate flight of shallow steps with the combined technique worm and monkey. I still felt faint after half an hour sitting. At 10 months I was promoted to a wheel-chai and at 1 year I could get in and out of it unaided; what more, when placed on a tricycle I could drive it eight yards round the garden, with the help of a hoe.

At $1^1/_2$ years I was travelling round the house and u the stairs on my feet, clinging to furniture or banister and I could walk round the garden clinging to a rop I did two miles on the tricycle every two or three day and in the next 6 months I increased my rides to eigh miles. I was beginning to walk alone, bent over tw sticks, and was learning to bicycle in a narrow corrido where there is less scope for falling. Most of my time wa still spent lying down. At $2^1/_2$ years I was walking up right, with one stick, for two miles or so and doing som digging and fuel stacking. I had discarded my abdomina belt. By 3 years I could do extensive heavy work, rid 40 miles on my bicycle, and pull myself up to my chi on a horizontal bar twice. I still lay down for hal the day. At $3^1/_2$ years I could walk ten miles without stick in five hours and could just get up from a fla surface, if it was not too smooth, without a stick.

It is now $6^1/_2$ years since my illness. Progress has bee slower in the last 2 years or so, from flagging enthusiasm and greater demands on my time. I can sit without slouching, stand erect, and keep my hips steady when I walk, so my gait attracts no notice. My maximum speed on foot is five miles in $1^3/_4$ hours. Stairs are still awkward, because I cannot yet stand on one leg with a bent knee.

* * *

From my own experience and other people's, the general idea that early return of voluntary muscle power is a good sign seems to be justified, for muscles that improve well at first maintain their lead and can be expected to become powerful if exercised. On the other hand, states like the following from a well-known textbook misleading: "Muscles that are going to recover i power will already have done so by the third th." All my muscles recovered more strength in the d 3 months than in the first 3, and much more in second 6 months than in the first 6. Almost all my les developed considerably more in the second year in the first, and most developed more in the second rs than in the first 2. My weaker muscles are still roving, with increasing returns for any effort I put them. My interest has returned, and dancing is the t target. A friend of mine is improving after 18 s, during 9 of which there was complete neglect. e seems to be no time limit to improvement of gth. The slowest progress in rehabilitation, apart the spontaneous recovery after the acute phase, is lly at the beginning.

he arch enemy of the poliomyelitis patient is stag- on, from the first day of his illness until he is sound n. Physically, mentally, and morally he must be fresh and stimulated by every means in the doctor's er. In the acute stage, frequent passive movements a great delight. One never loses the wish to move, the craving is strong in the early days. Frequent on and gentle massage all over are highly refreshing. warmth will prevent the cramps which come on when limbs are raised. With plenty of gentle handling the derness disappears more quickly than without, and dentally, it disappears quicker in the more exercised cles than in the others. Deep abdominal massage, icularly in the acute stage and the first few weeks, s to stave off the petty miseries of constipation and es and enemas, flatulence and indigestion. As soon the temperature drops every muscle should be exer- d to halt atrophy from disuse. Electricity is good at stage if the patient can stand it.

er the first month or so one's morale tends to en. Progress can be so slow that patients sometimes their escape from death. Initiative may well e altogether, with spasmodic revivals. Everything e when one begins to get out and about. People nd to the physically hampered, and there can be a humour in an old lady or an errand boy pushing tricycle up an incline or over a bridge. But nothing prevent humiliation when one has to spend hours, frequent rests and the next day flat in bed, elling a distance an ordinary person covers in a minutes.

he doctor who is an understanding friend can work ders—if he has the time and the necessary know- of mechanics. A special institution is a perfect ironment; here the patient will learn a lot from his ows, even if he is a child, and he will be instructed questions of apparatus. Failing that, the patient his family must be organised at home, but it is hard the poliomyelitis victim on his own to exercise himself he should. He rarely if ever does. Some muscles likely to be forgotten, as often happened with my k and abdomen. Careful and complete records, larly filled in, will reveal many little improvements would otherwise pass unnoticed.

A purposive mental or manual occupation is essential, erably with some responsibility, or under the orders outsiders, and if possible remunerated. It may be essary at times for the doctor to tell a patient who is his own to stop being sorry for himself and think about ething useful. He should be encouraged to be ependent and look after himself, even if he finds this cult. Poliomyelitis cripples in the same neighbour- d might derive much mutual encouragement if they t in touch with each other, making a sort of club.

If there are many weak muscles both doctor and ient may need to do much reading and discussing to n real progress. Fatigue is an essential part of the development of a muscle. Nature seems to provide a reserve beyond ordinary demands, and if this reserve is steadily encroached upon she builds up a larger one. It is the activity that the patient can only just perform, or cannot quite perform, that will bring back his strength. If increasing demands are not made, one can expect no improvement. Surely this applies to any training, physical or mental? At the end of a session of effort the muscles should be appreciably weaker.

Pain in a muscle as the direct result of exercise will follow a sudden large increase of effort, and will not return when that new effort is repeated. It appears to be without harmful significance; when my muscles became sore they gained strength faster than at other times.

There is a difference between developing strength and developing stamina, but both are important. Plenty of routine physical activity, carefully graded, will build up stamina. Special short sessions designed to produce rapid fatigue will increase strength. As the patient recovers the short sessions should be increased in number, and he should be encouraged to move more rapidly. The American idea of putting weights on the patient—lead insoles, for instance, or a bag of shot round the ankle or wrist or elbow—is excellent. Progress is a matter of compound interest: a stronger muscle gains strength more rapidly than a weak one. The dreary work of the first few months may seem entirely futile, but it is indispensable.

Fatigue can be dangerous if it is cumulative, and there is some justification for the usual concern. Muscles can shrink and the patient become a nervous wreck. There must always be sufficient rest to correspond to the exercise. If the routine is so planned that the muscles recover their best strength at some time every day, or even every two or three days, there is nothing to fear. When he is not taking exercise the patient should spend most or all of his time flat in bed. Meals can be taken quite conveniently from a tray on the chest; the head should be as vertical as possible, with the shoulders flat on the bed. This posture is much more comfortable than it looks, brings no deformity, and was my favourite one for over three years. The extra energy saved is surprising.

If the diet is poor, progress will slow down, for there is something peculiarly depressing about trying to exert oneself on poor food. A full diet, with sufficient minerals and vitamins, makes an obvious difference; and extra iron and vitamin C now and then are a help.

The most convenient apparatus for home use is an overhead hook or beam, at a good height. To this spiral springs (much handier than weights and pulleys) can be attached, or plain cords. Limbs mounted in slings can make any movements needed, without the influence of gravity, if the patient is in a suitable position. Gravity can be gradually brought into play by lowering the fixed point and shortening the cords. If the shoulder muscles are recovering, a back brace is a hindrance rather than a help. Very little attention will prevent scoliosis or other deformity. Good gutter splints are comfortable for *resting* the legs in, but there should be no flexion at the knee, however slight.

I found a 'Dunlopillo' square more comfortable and reliable than an air ring. But, when one's back muscles are negligible, deformity will result if the pelvis is kept raised, so I used a flat pad of sponge rubber, covered in soft cloth, with a hole just large enough to accommodate the prominent part of the sacrum.

* * *

To sum up: There is no apparent limit to progress. The beginnin [illegible] the slowest. A special institution is de[illegible]rging more [illegible] is absolutely necessary for muscle d[illegible]hould he make t[illegible]rest and proper diet are also essential. J[illegible]tion ready finish general stagnation can be the patient's [illegible] of this argument especially from the integration of medical education with the national requirements for medical personnel.

I am indebted to the Hon. I. F. Kononenko, formerly Minister of Care of Health for the Ukrainian S.S.R., and Dr. Lev. I. Medved, now Minister, who have accorded me every facility; Prof. S. S. Kagan, chair of organisation of health, who has been my guide, philosopher, and friend; Professor Kalchenko, director of the Kiev Postgraduate Institute; Docent Kalainichenko, director of the Kiev Medical Institute, and all the other professors, docents, and physicians who have supplied me with information.

MEDICAL PROTECTION SOCIETY

Sir Ernest Rock Carling, the president, addressing the annual general meeting of this society held in London on Sept. 29, said that it had had another successful year: the membership had steadily increased and the financial position was sound. With the coming of the National Health Service the future was uncertain; but nothing in past experience suggested that attacks on the profession by disgruntled patients would grow fewer. Government departments had a tendency to compromise, without clearing the character of the professional person attacked; and lawyers were inclined to exaggerate the alleged shortcomings of the medical man, attributing to his neglectfulness and hard-heartedness —if not actual malice—the entire effects of accident or disease. The costs of medical protection were likely to rise rather than fall; but the society faced the future with confidence and solid assets. One advantage it might gain from the National Health Service was that the doctor would have to keep good records; for in the past many a case had been prejudiced for lack of notes.

Remarking on the trouble caused by broken hollow needles, Sir Ernest said that in all cases where the society had submitted the fragments to a metallurgist a manufacturing defect had been found. He hoped for improvement of manufacture, but also reminded members that needles must not be cleaned with, or immersed in, solutions of iodine, which even in minute traces could erode and weaken them. Another source of frequent trouble lately had been fracture of the jaw during dental extractions. This was by no means always the result of bad work: it was often due to osteomyelitis, which could be properly treated only by removal of the offending teeth. Nevertheless wherever there was a possibility of osteomyelitis leading to fracture it was important to radiograph the jaw first.

Where there was some mishap the doctor or dentist was often uncertain whether he should tell the patient (or the relatives). In the vast majority of cases the patient should be informed: to give the facts never redounded to the practitioner's discredit.

The objects of the society, said Sir Ernest in conclusion, were not merely to protect medical men: having the same objects as medicine as a whole, it was concerned with prevention as well as defence, and it sought at all times to encourage correct professional behaviour.

The society's expenditure for the year 1947 averaged 23*s*. 3*d*. per member, though the subscription remained at £1. With accumulated funds standing on Dec. 31 at £112,991, the resources available for protection were £145,816, and the society is reinsured to an unlimited amount against adverse costs and damages exceeding a specified amount during any one year.

Tribute was paid at the meeting to the late Mr. G. F. Stebbing, who has been succeeded as chairman of council by Dr. G. M. Stoker. Sir Robert Hutchison spoke in warm terms of the service rendered to the society by Sir Ernest Rock Carling, who was re-elected president.

Mr. W. M. Mollison will serve again as treasurer.

Dr. A. R. French was appointed secretary of the society in place of Dr. R. W. Durand, who is going to Belfast as medical superintendent of the City Hospital.

From my own experience and other people's, the genera
idea that *early return of voluntary muscle power* is
good sign seems to be justified, for muscles that impro
well at first maintain their lead and can be expected t
become powerful if exercised. On the other hand, state

Letters to the Editor

CHRISTMAS GIFTS

SIR,—I appeal once more to members of the medical ession to help those who are dependent on others extra comforts. The beneficiaries of the Royal cal Benevolent Fund are in such a case. They are aged or infirm practitioners, their wives, widows, children, and, through no fault of their own, find selves in need of help.

I hope that subscribers to the fund will send donations provide a little extra cheer at Christmas time, and I estly beg those who are not subscribers, not only to d Christmas gifts but to become regular supporters of fund. A special effort to obtain new subscriptions urgently necessary because certain medical bodies, h as the panel committees, which used to make erous contributions, have gone out of existence with National Health Service Act.

Donations and subscriptions, marked "Christmas ts," should be sent to the Secretary of the Royal dical Benevolent Fund, 1, Balliol House, Manor lds, Putney, London, S.W.15, and will be gratefully nowledged.

WEBB-JOHNSON
President, Royal Medical Benevolent Fund.

EXSANGUINO-TRANSFUSION IN ACUTE LEUKÆMIA

SIR,—Dr. Maycock (Sept. 18) does not understand what grounds I made the statement that "it is possible to obtain very large quantities of blood at y one time in England." My reason was a simple one: attempt was made and was unsuccessful. True ough, I did not apply to any of the regional transfusion tres: I left that to a junior colleague.

If Dr. Maycock had read my preliminary communica-, he could not have failed to notice that I emphasised , as far as is yet known, the beneficial effect exsanguination-transfusion is only temporary; but, rtheless, the fact that remission does occur suggests mber of fresh avenues of research.

m, of course, grateful to Dr. Maycock for reminding the difficulty of getting certain groups, but I must t that I am well aware of the elementary facts he arly sets out. It is, of course, true that the decision try exsanguino-transfusion in acute leukæmia is ys a difficult one; and, in fact, much of the onus to be placed on the relatives. But what is meant by ing that "exsanguination-transfusions should always deliberately planned in consultation with the regional od-transfusion officer" I frankly do not know. Surely, is the task of the physician to plan the treatment, ays, of course, subject to the availability of the rapeutic agent—in the present case, blood.

London, W.1. A. PINEY.

H. INFLUENZÆ MENINGITIS TREATED WITH STREPTOMYCIN

SIR,—There are two statements in Dr. Smythe's herwise admirable paper of Sept. 25 which may lead to me misunderstanding regarding the value of penicillin eatment in this condition. On p. 485 he writes, with gard to the 12 cases referred to the London Hospital r streptomycin treatment: "In 10 of them penicillin sulphonamides had been administered before admis-n; but these drugs had not controlled the infection d *H. influenzæ* was still present in the cerebrospinal uid or blood." Page 490 contains the statement: Though penicillin combined with sulphonamides does t appear to be so effective as streptomycin it may yet prove useful in combined therapy."

From this it would appear (1) that adequate penicillin treatment had been given to 10 of 12 cases and that this form of treatment had failed where streptomycin succeeded; and (2) that combined penicillin-sulphonamide treatment is inferior to streptomycin therapy either alone or combined. Neither of these assumptions is substantiated in Dr. Smythe's or any other paper published hitherto. As regards (1) it is evident from the case-histories given that 7 out of the 8 cases previously treated with penicillin had been give no intrathecal penicillin or intrathecal inject inadequate amounts. The one case (no. 2) whic adequate penicillin-sulphonamide treatment was p to have a sterile C.S.F. before commencing streptom therapy. It is an open question, however, whether this case complete restoration of health might not hav resulted if streptomycin treatment had been started earlier in the illness.

This comment is not intended to make a case for combined penicillin-sulphonamide treatment as against streptomycin therapy either alone or combined. All one is justified in saying at this juncture is that there seem to be special merits in each of the proposed forms of treatment. Further comparative work appears necessary for the evaluation of and the definition of indications for the various methods of therapy now available.

K. ZINNEMANN.

Bacteriology Dept., School of Medicine, Leeds.

PROPRIETARY MEDICINES UNDER THE ACT

SIR,—Mr. Godding's article of Sept. 18 (p. 465) is interesting, but it leaves out many aspects of the case.

First, I believe that the machinery for investigating excessive prescribing under N.H.I. was prompted by the fixing of a total limit to the drug fund, and when the chemists' accounts rose above this figure they were only paid part. Consequently the chemists were particularly keen to see that the cost came down. Nevertheless, is there any evidence that this machinery has been abused and tended to prevent proper medical treatment? What about the cases on adrenal cortical extract running into hundreds of pounds per annum per case? In one of these cases the doctor wrote to the insurance committee before prescribing and was assured that he could order this. Consequently I feel that the manufacturers of proprietary preparations of the highest ethical standing of this type have little cause for apprehension.

But there is another class of preparation. The Chemists' Federation appears to be trying to impose standards on preparations it admits to its list, which are of course less rigid in the case of ethical proprietary preparations because the doctor is expected to examine their formulæ, &c., more closely than an uneducated patient would do. It does not, however, so far as I know, claim to have vetted all the previous inclusions to the list by the same measure, and, seeing that the federation was principally founded both for price-protection and limitation of sale of medicines to chemists, it cannot completely serve both masters—i.e., the trade and the medical profession. The question of standards should be dealt with by a separate body, free from criticism on this score, on the lines of the American Medical Association arrangement.

Personally I am more interested in the standing of the makers than in prescribing a proprietary article. If, for instance, I order sulphanilamide I do not mind whose make is supplied, provided it is a reliable firm possessing full facilities to ensure that the preparation is proper. I do not like a mixture of say quinine sulphate and quinine alkaloid being supplied for quinine alkaloid, whatever the explanation of the offending firm; but here we are getting off the question of proprietary medicines.

Nor do I like the guarding which still occurs in the formulæ of some proprietary preparations. I am referring to ingredients not in the *B.P.* or *B.P.C.* which on close examination appear to be extracts of mistletoe and the like. What evidence is there that they have any therapeutic effect?

The interest of the federation is to promote the sale of its members' proprietary articles. Is this the real interest of pharmacy? If practitioners are to be encouraged to prescribe proprietary preparations then there is little necessity for pharmacists to be properly trained, and it is in effect a further development of "multiple" pharmacy. Should the chemist be encouraged to keep the raw materials in stock so that he can make, on demand, the exact preparation required by the doctor, charging more for extemporaneous manufacture? Or should he make the patient wait and obtain the preparation ready finished from his supplier? The outcome of this argument is obvious, and is indeed partially

In England Now

A Running Commentary by Peripatetic Correspondents

AFTER reading the correspondence in THE LANCET I have been asking myself just what constitutes a good secretary for a consultant. First, she must be able to take notes at a high speed. For this she will require acute and accent-filter hearing, flexible fingers, courage (the girl who blenches at the thought of confining the shorthand outline for "dysdiadochokinesia" to one line of her notebook won't last long), and a better fountain-pen than has yet been invented. Still more important, she should be able to read her shorthand. She should be able to spell medical terms not only correctly but with that brand of correctness *most acceptable to her employer*—e.g., *clinique*, clinic; leukocytosis, leucocytosis—and her typewriting should be accurate. In medical typescript trifling errors and omissions assume alarming proportions and can be misleading in a manner likely to lower the dignity of the writer: "No puss was found in the urine but some cats were present." A knowledge of Latin is helpful, but the scholarly secretary should never seek to minimise her shortcomings by murmuring in the chief's ear, "*Humanum est errare*"; he would agree that to err is, but not that secretaries are.

It is not desirable that a secretary should have a sense of humour. If, for instance, in a moment of illumination she suddenly sees the heart specialist's reiterated advice to his patient to "learn to take things quietly" as lesson 1 of a correspondence course in burglary, she will be so busy visualising the students, plus masks and dark lanterns and minus boots, striving to take things quietly that she will get the dosage of digitalis wrong; and, unless her chief reads his letters as well as signing them, will probably end on the gallows. She should, however, have enough imagination to tell her what the doctor meant to say when his dictation is more than usually elliptical, but not enough to enable her to identify all the symptoms of all the patients with the sensations experienced and the activities engaged in by her own body.

She must be clairvoyant. How else will she bring to the chief's notice engagements he has omitted to tell her he has undertaken? How else will she "remember" to get the results of an X-ray examination that she didn't know had been done? Above all, how else will she know to refrain from rendering accounts for fees that were paid to him at the time of consultation and never spoken of again? It is useful and sometimes essential to be able to read the chief's writing; but that is asking rather a lot, and I have found that surgeons may even like to be appealed to for an interpretation. They get some sort of psychological kick out of feeling that they have stumped *one*—something akin, I suppose, to having planned the perfect crime. Freud would know.

Consultants sometimes want their secretaries to attend them at hospital, and that brings up a whole series of new difficulties, the most outstanding being the sisters. To cope with these calls for tact, technique, and tolerance; the secretary who can convey the chief's instructions to his ward sister without producing an immediate reaction of resentment to herself as intermediary, antagonism to the idea contained in the request, and obstructiveness to its being carried out, has got what it takes. If she can, in addition, extract from one of the secret sisterhood the information she requires without effusion of blood and tears, that secretary is worth her weight in coal.

Every man had an unblemished medical history, and clinical examination has so far failed to detect any o the many abnormalities listed in the 6-page bookle which has to be duly (why "duly"?) completed. Th swelling totals of "Normal's" and "No's" made m wonder if I was losing my touch. However, the othe day an elderly member of the force came along fo examination with a view to retiring on pension. H had plenty wrong with him, and fruitful results obtained in almost every system. His past reco illnesses filled a typewritten sheet, which showed evidence of illegible writing on the part of his and praiseworthy attempts to decipher it on the of the typist. "Turunculosis" of course was furunc and "Unpitijo" was resolved into impetigo, "Phonjijitis"!—what an admirable term for the j ness which betrays a doctor in non-medical com when the telephone rings! The best we could thi was pharyngitis, but as the would-be "retiree" he never had a sore throat the matter rests here.

* * *

It may not be good for us peripatetic correspon that, secure in our anonymity, we can ventilat opinions without contradiction, or expurgate ou grievances without denunciation—but it is very plea I wonder sometimes how far our identity is suspe Notwithstanding all precautions, the choice of su or some eccentricity of style often betrays a w But though they may suspect, our victims cann sure. So we may mingle with colleagues whose quid we have limned, and sympathise hypocritically their grumbles while inwardly preserving the opi we have recorded.

As I expected, my criticism of eminent lect excited some protests. I am impenitent. A fo lecture, such as those delivered at the colleges, sh be not the mere reading of a manuscript, but a thorou prepared oration delivered with the aid of a few not even none at all. To the silly objection that the Ad has been learnt by heart, I would reply that th following the practice of all great orators inclu Cicero, and is in any case no small achievem Admittedly the preparation demands a great dea trouble, and the performance a great deal of cou The fear of a complete blackout can never be ent absent even in the experienced accomplished perfor yet discipline demands that the lecturer should confident enough to refrain from carrying a manus in his pocket—just in case. The perfect expon is he who is so expert in his subject and so saturated w it that his uninterrupted fluency gives the impress of impromptu delivery. For this not a little of histrionic is essential.

Is it worth while? That must be a matter of opin I know at least three members of our profession have demonstrated their ability to perform such a t de-force, and if they acquire a sense of satisfact commensurate with the admiration of their audien they are well rewarded for their trouble.

COMPENSATION FOR PRACTICES DEPLETED DURING WAR SERVICE

SIR,—In 1939 many general practitioners conceived it their duty to join the Territorials or the Volunteer Reserve of the Royal Navy or the R.A.F., in readiness for an expected blitzkrieg. During their service they lost very heavily financially. The pay of a lieutenant (or flying-officer) was about £380 a year, of a captain (or flight-lieutenant) about £430, and of a major (or squadron-leader) about £640, plus small marriage allowances where applicable. Many had heavy civilian and family commitments to meet.

They returned in 1945 or 1946 to practices which were [illegible] depleted (unless they were fortunate enough to have partners to look after their interests while they were away). In many cases there has been only one full accounting year since their return; in no case can there have been more than two years. For purposes of compensation, therefore, it would be seriously wrong to assess the value of their practices on these difficult first years of the post-war re-start.

It is understood that such cases will be specially considered; but they are so numerous, and so obviously entitled to fair play as a right and not as a concession, that some general principle should apply. I submit that the only fair assessment is to take the pre-war value of the practice, and to add to it a proportion equivalent to the average increase from 1939 to 1947 of the value of the practices of those who, for good or bad reasons, remained behind. This proportion could easily [illegible] out by the tax authorities, but I estimate that it [illegible] about 70%.

Only so can these men who have been penalised for [illegible] war service by loss of income escape being further penalised for that service by assessment of their life's [illegible] at figures which bear no relation to what their [illegible] could have been had they ignored the call [illegible].

PRE-WAR V.R.

HOW MANY NURSES?

SIR,—Your leading article of Sept. 25 deals with [illegible] problems raised in my report on the nursing services.

I venture to suggest that you have failed to appreciate [illegible] essential point in the argument in chapter IV of my report. This point is that the absence of any demonstrable correlation between the nurse-patient ratio and duration of stay in, say, tuberculosis sanatoria in no way invalidates the criterion I have adopted of duration of [illegible] as an index of nursing (or medical) effectiveness. [illegible] does it destroy my hypothesis. Just as the presence of correlation between these variables in general hospitals may be taken to indicate the effectiveness of nursing [illegible] in these institutions, so the absence of correlation in sanatoria may be taken to indicate a corresponding ineffectiveness of nurse training or treatment in sanatoria. Consequently, it is, I submit, incorrect to speak, as [illegible] do, of "conflicting evidence" or "equivocal results." [illegible] the contrary, all the results seem to me to be concordant. Nor is it correct to say that the "only" evidence relates to general hospitals. The fact that the data—the latest available in published form—refer to [illegible] is beside the point.

You say that few will agree with the assumption that duration of stay is an objective measure of the task of nurses and doctors, because duration of stay is also affected by other variables—viz., type of illness, facilities [illegible] investigation and treatment, pressure of waiting-lists, provision of convalescent homes, and quality of diet. Is this not rather like arguing that we cannot judge the health of school-children by their stature, because stature is also affected by hereditary and other factors? My contention (see para. 89 of the report) is that there should be a functional dependence of duration of stay on staffing ratios when all other factors are held constant.

I had hoped that this would be abundantly clear i text. To pursue the analogy, this would be like that the stature of school-children is a measure of health when hereditary and other "disturbing" fac are controlled. Furthermore the report gives conside tion to the possible effect of "other" factors which yo article implies have been overlooked. Indeed, when data are available, evidence is adduced to show that some of these factors (e.g., types of illness) have no apparent effect on the calculations.

Lastly, may I add that that it is no criticism to say that no solution is offered for the immediate nursing shortage. Our terms of reference explicitly excluded short-term palliatives and were confined to long-term measures.

Dept. of Social Studies,
The University, Leeds.   JOHN COHEN.

DIAGNOSIS OF PEPTIC ULCER IN GENERAL PRACTICE

SIR,—The possibility of successful treatment of peptic ulcer varies inversely with the chronicity; hence early diagnosis is most important. In the incipient stages the clinical picture is not always clear-cut, and it is not always practicable, particularly in industrial and in rural practice, for the family doctor, to whom these cases usually come first, to submit each one to radiography, which moreover at this stage is often negative or inconclusive. To meet this difficulty I have for many years used the Gregersen[1] benzidine slide test (G.S.T.) for occult blood in the fæces. It is a modification of the usual laboratory benzidine test in which it is claimed that the sensitivity is reduced so that the ingestion of hæmoglobin-containing food in normal amount does not produce positive results. It is as simply and rapidly carried out as are the usual tests for sugar and albumin in the urine, and is therefore eminently suited to general practice.

When in 1941 supplementary rations were granted for peptic-ulcer patients the opportunity was taken to investigate fully, including the G.S.T., those patients not previously examined who now applied for the requisite forms. My partner and I (the population is mainly industrial) thus made a fairly comprehensive survey of our patients with symptoms of peptic ulcer and other pathological conditions of the alimentary tract.

All cases diagnosed during the past ten years, in which both X-ray and G.S.T. findings are available, have been collected and analysed. There are 123 cases: 102 of peptic ulcer, and 21 of other alimentary conditions. I have omitted all cases of neoplasm in which on first examination the diagnosis was beyond doubt, and I have included a few ulcer cases diagnosed before the period under review, in which there are still active symptoms.

The G.S.T. findings have been compared with the X-ray and clinical findings, including in some cases confirmation after operation. Both the G.S.T. and X-ray findings were positive in 69 (68%) of 102 ulcer cases, and in 18 (86%) of 21 other conditions. The G.S.T. was positive and the X-ray findings negative, but clinical observations and subsequent history confirmed the positive diagnosis, in 19 of the 102 ulcer cases and 3 of the 21 other cases. The G.S.T. was negative, and positive X-ray findings confirmed the clinical findings, in 14 of the 102 ulcer cases, but in none of the 21 other cases. Thus there were 22 cases which might have been missed if the G.S.T. had not been used, and 14 cases in which the G.S.T. did not support the diagnosis.

In more than two-thirds of all cases both the G.S.T. and the X-ray findings were positive. Of these 87 cases, all but 22 were first diagnosed with the G.S.T. Where the two tests gave differing results, the G.S.T. was right rather more often than the X-ray findings: 22 cases and 14 cases respectively. Of the 19 ulcer cases with initial negative X-ray findings, 3 cases radiographed again after an interval because of a persistently positive G.S.T. gave a positive result, and 2 cases, one of neoplasm and the other of diverticulitis, both of them with initial negative X-ray findings and re-examined for the same reason, subsequently gave positive X-ray findings. These 5 cases are perhaps among the most significant in the series.

evident today. How many pharmacists make such things as Parrish's Food themselves?

Finally I would like to make a suggestion regarding future formularies. From the doctor's point of view a formulary covering the whole country has disadvantages. There was a tablet (tab. febrifuge) in the *North of England Medical Formulary* which was very popular. When the *National Formulary* came into being this tablet's name was first altered and later the strength was halved. Here tab. febrifuge are still ordered, and owing to this name being used on a prescription form the practitioner can get the original formula and the pricing office can deal with the prescription. So in any major alteration of formulæ I would suggest that a new name be adopted for the new preparation so that this can still be the case. I know this cuts across the present accepted views regarding naming (see preface to *N(W)F*) but I have outlined the practical reasons for this modification.

Seaham. A. FORSTER.

CHARMS

SIR,—Dr. Inman's observations (July 10, p. 77) remind me of a case encountered 6000 miles away.

In 1931, when I returned from Great Britain puffed up with the possession of a membership, a railway-ticket collector in my native town of Dadu, Sind, hearing of my recent exaltation, came to consult me. His face was covered with warts—more numerous about his chin, which made shaving an agony. His disappointment was as great as my chagrin when I told him that we, the English doctors, had not yet found a cure except by a knife or caustics which were out of question in his case. After about a month I happened to meet him again and was astonished to see that his face was completely clear of warts. I inquired the name of the remedy, and this is what he said. "Sir, after having seen that even the biggest doctor could not help me, I went to Kotri, a village about 100 miles away, where I had heard that an untouchable class of woman, 'Chuhri,' could cure my disease. She warned me that I would not be able to stand the ordeal, but I assured her that I would. On this she drank some dirty-looking water, gargled, and ejected it in a stream all over my face. Of course my repugnance was extreme, but not so great as my disappointment when you said that you had no cure. She repeated this process for three days, and at the end my face cleared up like magic."

Though amused by this story, I could not but feel humiliated; for the proof of pudding lies in eating, and I had eaten the humble pie.

Bellary, India. P. V. KARAMCHANDANI.

LETTER TO A NEPHEW

The following is the final letter in this correspondence:

MY DEAR UNCLES,

I am very grateful for your friendly concern in my future and for the compliment you pay me in addressing me as a mature, level-headed, person. As such, I hope I may put forward my own views without appearing presumptuous or in any way unheedful of your counsels.

You will understand that I have no preconceived ideas whatever about working within or without a "service"; so I tend to remain unmoved by arguments which are based on these ideas. It seems to me, on the contrary, that a "service" will become what I and my colleagues make it, and that judgment might well be deferred until we have had our chance. In Sweden the profession have made a success of State-controlled medicine, and I see no reason why we should not do as well.

I agree with my old-fashioned uncle that any claim to a vocation would ill become me at this stage; at the same time, I feel that the job most worth doing would be one which most directly concerns itself with the public weal, and this implies ideals of a kind. They are, I hope, appropriate to my age and my capacity, and I shall be very happy to devote myself to their realisation as opportunity allows. I expect help rather than hindrance from the framework of the National Health Service; for, short of assuming that it is designed against the public weal, it must be intended as my servant, not my master. Its aims so far as I can gather, are the same as my own.

Forgive me, but what would you say *if* I suggested that any circumstance whatever might suddenly induce your own patients to regard you as mere "mechanisms" instead of the very able doctors you are? I take it that you ridicule th notion that any change of label or wrapping could affect th quality of your work in the slightest degree; please allow m to feel as unchangeable as you know yourselves to be. If t "practical" view cannot respect this deep conviction of min then I am afraid I feel bound to reject the practical view.

My solemnity must strike you as rather pompous, but thought that I could thank you best by taking your remar very much to heart and answering them with all the [illegible] which I feel they deserve.

Your grateful and affectionate nephew,

CHARLES.

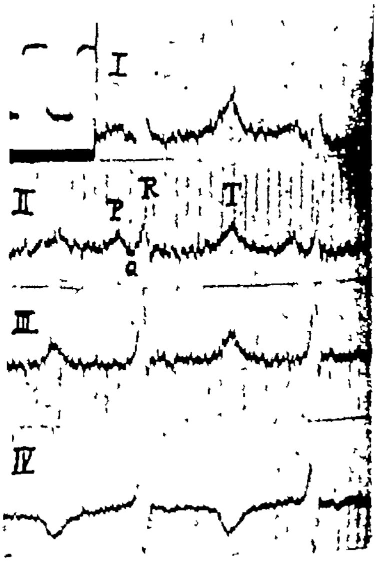
PRIVATE PATIENTS NOT ADMITTED

SIR,—The teaching hospitals, which have consultin rooms available for their medical staff, provide experience analogous to that of allowing private patien in health centres. This is how it works. A patient w known to me was sent a few days ago by her doctor t the hospital to see a consultant. There she was tol that it would be three weeks before she could have a appointment. But she could be seen as a priva patient if she liked to pay three guineas. As she was a good deal of pain she consented, and the time w fixed for two days later. *Incidentally, if she had go* to the non-teaching hospital, which was nearer to h home, she would have seen a better man without del or the payment of any fee.

LAY OBSERVER.

DIAGNOSIS AND TREATMENT OF PANCREATI NECROSIS

SIR,—An electrocardiogram on the sixth day of acu pancreatic necrosis, which had been recognised as su during the patient's life and confirmed by necrops showed a pronounced elongation of the Q–T interv (Q–T = $^1/_2$ sec. with the pulse-rate 80 per min.), increased T deflection, and a slackening of the hear action, without any distinctive signs of damage to th heart muscle (see figure), a type of electrocardiogram which is usually described as tetanic. Thinking that these electrographic changes might be due to a lowered blood-calcium level as they are in tetany, I decided to check this in the next case of pancreatic necrosis, and found both the altered electrocardiogram and a lowered blood-calcium level as expected. The patient was treated with intravenous injections of a 10% solution of calcium gluconate 10 ml. twice daily, con trolled by estimation of the blood-calcium level. Sh began to improve continuously from the first day o treatment and recovered within three weeks.



The lowered blood-calcium level I attribute to th binding of the body calcium at the foci of fat necros and to the lack of absorption of calcium from food becaus of persistent vomiting. I suggest that the formation o foci of fat necrosis causes a lowered blood-calcium level, which in turn intensifies vagal tonus, producing an elongated Q–T interval, increased T deflection, and slowing of the heart. The more numerous and more extensive the foci of fat necrosis, and the faster the rate of their formation, the more pronounced will the electrocardiographic changes be. Consequently electrocardiography coupled with the determination of the not told until after the final appointments have been made. It would avoid much unnecessary suspense if ssful candidates could be informed as soon as short list is selected.

May I also make a plea for a little thought and con- ation towards the candidate, whose time, after all, y be just as important as that of the interviewing mittee. I was recently summoned for an interview telegram and letter, both of which were dispatched y-eight hours before the time of the meeting, but n weeks after the closing date for applications. I pened to be on holiday at the time and received both munications approximately two hours before I was to appear; but as I was in Scotland and the inter- ing committee was in Southern England, we were ble to meet. On another recent occasion I was t waiting, with the other candidates, for two hours the time arranged, because the chairman of the mittee failed to turn up!

REGISTRAR.

MUMPS WITH SEVERE COMPLICATIONS

—That one general practitioner should meet with consecutive cases of mumps with grave complica- within three weeks is rather extraordinary. Both were treated at home.

CASE 1.—A clerk, aged 36, developed bilateral salivary is on July 18, 1947. Five days later he had left tis and epididymitis with considerable constitutional oms, which increased in severity throughout the day. July 23 he developed violent headache, slight delirium, abdominal pain, and half-hourly vomiting, with blood ucosa in the vomit.

On examination the patient was very ill and unresponsive yellowish conjunctivæ, temperature 103·2°F, pulse-rate respirations 24 per min., nothing abnormal in the chest, tender abdomen, especially the left hypochondrium. ine gave a green deposit with Benedict's solution.

pancreatitis was diagnosed. All attempts to give by mouth failed. Vomiting persisted. Pethidine and hyoscine gr. $^1/_{150}$ were given, without producing lief.

July 24 his general condition was much worse, and he less with very severe abdominal pain; left testicle bigger; delirium more continuous; temperature F. A drip infusion of 5% dextrose in normal saline n was set up through a Hamilton Bailey cannula into right saphenous vein. Improvement in the general on was noted within an hour of starting the drip. ine was passed that day. The evening temperature 103°F. 'Omnopon' gr. $^1/_3$ and scopolamine gr. $^1/_{150}$ given twice during the night, with great relief and tion in restlessness.

July 25 the patient had had a quiet night and improved h in his general condition. Temperature 101°F. The nt passed urine. A litre of 5% dextrose was given and ond litre, of 10% dextrose, was begun. The patient d to take water by mouth. Vomiting ceased. By the second litre of dextrose solution was finished. pint of concentrated red cells (supplied by the South don Blood Transfusion Service, Sutton) was given, and cannula was removed. There was no abdominal pain headache. Temperature 101·2°F, pulse-rate 86. The nt was drinking well. 'Sodium amytal' gr. 3 was n at night.

On July 26, after a good night, the patient's temperature 98·8°F. Thereafter recovery was rapid and uninterrupted, t for thrombosis of the saphenous vein. Since 10% rose was the only solution available for the second litre ch this is twice as strong as what I normally use) the of venous thrombosis had to be taken.

CASE 2.—A pipe-layer, aged 26, was seen on Aug. 5, 1947, bilateral salivary adenitis. He was not very ill, and tablets of aspirin and opium were prescribed. Next he had right orchitis and epididymitis, with a great in general malaise. Temperature 103°F. A sus- ry belt gave relief. On Aug. 7 the temperature was °F, and the testicle was more comfortable, but the nt complained of abdominal pain, a severe headache nd the eyes, and generalised myalgia.

On examination the right inguinal region was tender, but abdominal wall was lax and not generally tender.

On Aug. 8 the patient began to vomit and t ocular headache became unendurable, making hi and at times shriek out. He had intense photop and two mild jacksonian fits. Nothing abnormal found in the abdomen and chest. Neck rigidity present, and Kernig's sign positive. The pupils react to light, but there was bilateral nystagmus. Temperature 103·6°F, pulse-rate 84. Meningo-encephalitis was diagnosed. Drinks of 5% glucose in small amounts were given. Omnopon gr. $^1/_3$ and scopolamine gr. $^1/_{150}$ half intravenously and half intramuscularly were given, with immediate relief. In the evening the patient was crying with headache, and nystagmus was increasing; he had another fit, with momentary loss of consciousness. Temperature 104·4°F, pulse-rate 68. Omnopon and scopolamine were given subcutaneously.

On Aug. 9 the patient had had six hours' sleep during the night, but the headache was again as intense as ever, and he was vomiting, not drinking, and passed no urine. Temperature 98·2°F. Potassium citrate was given two-hourly. Photophobia increased. Blackout curtains were put up, and two scarves were placed over the patient's eyes. He shrieked if a chink of light showed under the scarves. Lumbar puncture showed the cerebrospinal fluid (C.S.F.) to be under pressure of 160 mm. H_2O; 10 ml. was withdrawn. This was followed by immediate relief. Within ten minutes the scarves were removed from the patient's eyes, the curtains were drawn back, and the patient chatted happily. The C.S.F. contained 12 lymphocytes per c.mm., the other constituents being within normal limits. The patient made an uninterrupted recovery.

Interesting points are: (1) the severe constitutional symptoms in both cases as soon as the testicle was affected; (2) the fact that both patients had orchitis as a prelude to much more grave complications; and (3) in the second case, the fact that, after the fever had dropped by crisis, the symptoms of intracranial pressure increased, and responded dramatically to lumbar puncture.

Haywards Heath. H. DERBYSHIRE BROWNE.

SUBACUTE BACTERIAL ENDOCARDITIS

SIR,—I read Professor Bramwell's article of Sept. 25 with interest. No doubt the most important factor in the prognosis, apart from penicillin, is the duration of the disease. Professor Bramwell and recent American workers have stressed this. I think the lack of close correlation between the in-vitro sensitivity of the organism and the dosage required is intimately related to the duration.

It is well known that small doses of penicillin will rapidly clear the blood of streptococci, and the mechanism is probably a bacteriostatic action associated with circulating antibodies and phagocytes. In the vegetations, which consist of relatively avascular and necrotic masses of platelets, fibrin, and streptococci, penicillin must act predominantly as a bactericidal agent. Obviously, the duration of the disease will largely determine the size and extent of these vegetations, and thus indirectly the dosage necessary. There can be no fixed dosage schemes in the treatment of this condition.

We have at present two cases in hospital who are being given one million units three-hourly for six weeks.

General Hospital, Birmingham. M. J. MEYNELL.

A DIPLOMA IN VENEREOLOGY

SIR,—Like many others from distant countries of the British Commonwealth, I came to Great Britain for postgraduate instruction and additional experience in venereology. Although I have studied, worked hard, acquired knowledge, and gained experience under some of the best teachers of this country, it seems that I must eventually return without taking an examination for a diploma in this particular subject.

Almost every other branch of medicine has some special qualification obtainable by examination—e.g., D.C.H., D.I.H., D.P.H., D.T.M. & H., D.OBST. R.C.O.G., D.P.M., D.M.R., D.BACT., D.O.L., T.D.D., and D.O.M.S. I submit that the institution of such a diploma in venereology would help to raise the standards in a subject which has been greatly neglected by the profession, and whose importance has been shown repeatedly in peace

As regards ulcers only, both tests agreed in two-thirds of the cases; radiography failed in slightly under 1 case out of 5, and the G.S.T. in slightly less than 1 out of every 7 cases. For the other diagnoses the numbers are too small to give more than a strong indication: 11 cases of neoplasm; 5 which exhibited diverticulosis radiologically and had a positive G.S.T. (presumably cases of diverticulitis); and 1 case each of ulcerative colitis, regional ileitis, torsion of the cæcum, spastic colon, and pernicious anæmia.

Some clinicians still believe that, even with the G.S.T., hæmoglobin-containing food should be excluded from the diet for three days before the test. Maclean[2] strongly disagreed, and Ogilvie[3] found that, though meat in the diet might occasionally cause a faint colour with the G.S.T. after 30 sec., a blue or blue-green colour appearing within 30 sec. was proof of the presence of occult blood in the stool irrespective of the patient's diet, provided it had not included foods with a high blood-pigment concentration, such as black pudding, liver, and bone-marrow. However, because opinion on this matter is not unanimous, patients in this series were asked to abstain from meat-containing food for three days before bringing a specimen for examination.

The G.S.T. is *performed as follows:*

Powders are made up containing 0·2 g. of barium peroxide and 0·025 g. of pure benzidine. Put up in waxed paper they will keep indefinitely. Since different makes of reagent give various results, I have used benzidine 'AnalaR' (B.D.H.), which is specifically tested by the manufacturers against a freshly prepared 1 in 100,000 solution of blood. For the test one powder is dissolved in 5 ml. of a 50% solution of acetic acid 'AnalaR.' With a glass rod a small piece of fæces is taken from the centre of the stool and smeared on to a clean glass slide or a piece of white tiling. A few drops of the solution are then run on to the smear. A blue or blue-green colour develops within a minute if the test is positive, and the reaction is graded according to the depth of the colour and the time it takes to develop. Gregersen recognises three grades: +, a pale blue or green colour within 60 sec.; ++, a definite pale blue in 12–15 sec.; +++, a deep blue within 3 sec. Any colour developing after 60 sec. at normal room temperature is disregarded.

The patient is asked to bring a sample of fæces about the size of a bean or a pea, in a clean small jar. The test can then be performed in a few moments during the consultation. The powder, if preferred, can be made up in bulk. In a dark airtight bottle it will keep without deterioration for at least six months. I have tested the powder after that period, and found that it still gave a positive reaction in a 1–70,000 dilution of blood in water. For those doing the slide test for the first time it is advisable to have each powder made up separately till some idea is gained of the quantity needed for each test. It does not take long to learn the approximate quantity required and to tip it into the test-tube either directly from the bottle or with the tip of a spatula. There is no soiling of test-tubes with a fæcal suspension, and since only a small smear of fæces is used it can be easily cleaned from the slide with cotton-wool. In carrying out the test I have found the slides used by bacteriologists for examining hanging-drop cultures most useful.

To avoid so far as possible contamination of the specimen by blood from the rectum, anus, or vagina, it is wise to remove the portion of fæces for examination from the inside of the stool. Should it be necessary to examine fæces at once, some can almost always be immediately obtained by digital exploration of the rectum.

In estimating the value of the G.S.T. it is necessary to consider both its advantages and limitations. For the general practitioner it can be a valuable measure in the early diagnosis and treatment of alimentary ulceration. By its use he can sift and control his dyspepsias with more assurance and a better knowledge of the underlying pathology. Often it may enable him to decide more quickly which case requires the more expensive and time-consuming forms of investigation. By taking appropriate measures till all occult blood has disappeared from the fæces, it may enable him to avert the more serious complications of hæmorrhage and perforation. The minimal amount of blood requir give a positive result varies from one person to ano so a negative finding must not be considered concl and should always be judged in relation to the cli picture. A positive result is always significant; provided precautions have been taken to ex extraneous sources of blood, an attempt must alwa made to trace the cause of the bleeding.

Edinburgh. S. LIFE

HANDLING OF FOOD

SIR,—Both Dr. Stanley Turner's letter of Sep and the correspondence in your issue of Sept. 25 the need for cleanliness in the handling of food employers realised what damage can be done by deplorable methods to which attention has been d they would undoubtedly do something about it. efforts, however, will be nullified unless educatio food-handling is also given to their employees.

In the scheme we have in Guildford the volun efforts made by the employers and employees, in wi coöperation with the council, will it is hoped pro the most satisfactory results. We have frequent m ings between representatives of the health comm *and the food traders, and their employees, and* allows full discussion, in open session, of the reason all we ask in the way of improvement of methods better sanitation in the premises. A representativ the particular food trade is always present to a with the formation of the code of practice for his tr and in this way we can ensure that whatever we pro *in the way of improved conditions is a practical pro* tion. Food-handlers are shown why cleanliness on t part is essential, and how strict attention to cleanli protects the public they serve.

Guildford Hygienic Food Traders' Guild is thriv every trader who complies with the requirement given a certificate of such compliance and of member *of the guild, and every employee is given a* bu badge. By their certificate and badge the public see that the food trader and his assistant know t job and know how to produce clean food in a cle manner. I feel sure that this is the secret of succe the handling of food.

The collaboration of the public is also essential so t *no person suffering from a communicable* dis deliberately contaminates glasses or other articles u for the consumption of food. Education of the pu on these lines is urgently required.

F. A. BELAM
Guildford, Surrey. Medical Officer of Healt

SELECTED FOR INTERVIEW

SIR,—In the past, candidates selected for interv for posts in either voluntary or municipal hospitals h invariably been allowed reasonable out-of-pocket expe as well as train fares, when the distance travelled to place of interview warranted such payments. Ind some local authorities made use of a fixed scale of s sistence allowances based upon the number of hour absence from home. It now appears that, under National Health Service regulations, "there will refunded to candidates their third class railway or fares where they exceed five shillings. *In no circumstan can subsistence expenses be paid.*" (I quote the act words from a recent letter received by myself.) A b study of your advertisement columns, together wit "Bradshaw," makes it obvious that many candida may be away from home for twenty-four hours or e longer, assuming that they are usually selected fr several of the main teaching centres. This latest form economy is particularly mean since the majority vacant posts are in the house-officer and junior regist class, and the candidate for such posts can usually afford to be out of pocket, especially if he fails to appointed.

Secondly, there is considerable, and to my mind qu unnecessary, *delay in informing* candidates for m senior posts when their applications have been uns cessful. At present this delay may be anything up two or even three months from the closing date applications. The usual practice appears to be t candidates who have not been selected for intervi

3. Ogilvie, A. G. *Brit. med. J.* 1937, i, 755.

ted. the water drawn off in due course from various in the building, or even in neighbouring buildings, will polluted. Even if the stop valve is not closed, pollution take place if any leakage or draw-off in the system in the mains has the effect of robbing certain taps of

action which has been taken to deal with these contamination hazards has included: (*a*) correc- of the defects, if practicable, wherever found; amendments to plumbing codes and special regulations g cross-connexions and back-siphonage.

may be asked whether our own plumbing systems appliances may give rise to similar hazards to health. following points may be considered:

) Cross-connexions between potable and unpotable water t approved in our practice, but it may not be correct to that none exist.

The more serious back-siphonage hazards in America due to the combination of flushing valves with mains . The flushing valve is comparatively rare in this and only some of our areas permit mains supply to . It happens, however, that in those areas where is plentiful and can be supplied to taps directly from mains, flush valves are normally more acceptable because is less concern that they may waste water. Any develop- for the increased use of flushing valves, particularly coupled with the use, or greater use, of mains supply, to call for careful thought.

The development of new water-using devices gives in America, lest the hazards of back-siphonage, &c., be introduced. Similar care is needed here, and an that existing appliances, particularly in hospitals, reproach from this point of view.

) Although low-level inlets for baths and the like are no regarded as good practice in this country, it is common tap inlets below the flood rim, though above the . It is very difficult to estimate the degree of hazard, arising from this practice. Repeated inquiry was made ica as to the incidence of cases of contamination which be definitely attributed to tap outlets being above the only. The answer was usually, "We have no data kind. It is not possible, except by chance, to relate such a cause because back-siphonage is intermittent may pollute the water system, and lead to the drinking water, some time later—even in another building. only proceed on the basis of the probability that or later an arrangement which can be shown to permit ination in an experiment which simulates the condi- of practice will actually take place in a plumbing ation. The remedy is so simple and cheap that it should plied."

THE TOILET

The Central Council for Health Education has stated in this country every year there are over 5000 deaths diarrhœa and dysentery and that many of these are no doubt caused by the almost universal of not washing the hands after urination and ation.

In America, in hotels and restaurants of various grades, railway trains, railway stations, cinemas, &c., the ary equipment of toilet rooms was generally noted of a higher standard than in this country. Lavatory , with the important accessories of towels and soap, nearly always to be found close to the water-closet. was most commonly provided through a small tor in the form of a spring tap: several pressings of tap are needed to get enough soap for washing, and is therefore little encouragement to waste. Towels more usually of paper folded in packs (often in cial containers designed to discourage waste) and it rare to find supplies exhausted. A device to provide h towels in such a way that they could be used but removed was as follows:

The towels, packed in a neat pile, each had a chain attached one corner. The other end of this chain was connected to ring which passed over a rod running down into the used towel basket. On being released after use the to automatically into the basket.

There are very few public conveniences in America, it is normal practice for the public to use the toi rooms of hotels, automobile service stations, &c., whethe they are at the time customers of these places or not. This arrangement has advantages as well as disadvantages. In Britain, where hotels do not normally welcome non-patrons in their toilet rooms, the public conveniences are rather irregularly distributed and difficult for the stranger to find; they are often closed when needed, and seldom offer the same inducements to hand-washing after toilet.

Some differences between American and British plumbing appliances and fittings are instructive. The superior flushing of American closet pans merits attention. American practice usually favours cisterns for houses and valves for the larger buildings.

SOIL STACKS

Because of the severity of winters in America, soil stacks in that country are located inside buildings, whereas in Britain they are normally placed outside in order to give greater safety in the event of leakage. Some trouble has occurred in America due to leakages from internal soil stacks but almost no anxiety is felt about them in modern buildings in view of present-day standards of plumbing labour. Perhaps if similar confidence were justified in this country generally, there would be less opposition from sanitarians to internal pipes and concealed pipework.

Food and Drugs (Milk and Dairies) Act 1944

Owing to legal difficulties the Minister of Health will not after all be able to bring this Act into operation this year; in the meantime he asks authorities to renew licences under the Milk (Special Designations) Regulations for the year 1949.

Health in the Second Quarter

The quarter ended June 30, 1948, was remarkable for having the lowest infant-mortality rate (31 per 1000 live births) and the lowest stillbirth-rate (22·7 per 1000 total births) for any quarter on record and the lowest death-rate (10·3 per 1000 total population) for any June quarter. The birth-rate, which like the death-rate is based on the 1947 total population, was 19·0 per 1000, compared with 18·9 in the previous quarter, 21·9 in the June quarter of 1947, 19·1 in June, 1946, and an average of 17·5 for the second quarters of 1942–46. Births exceeded deaths by 93,355, not such a great excess as in 1947, but greater than in 1945 or 1946. Marriages totalled 183,954, which was 6000 under the five-year average. The Survey of Sickness revealed that in January, February, or March this year 67·2% of the people interviewed were either ill or injured, but the loss of work averaged only 1·1 days per month.

and in war in terms of individual suffering and loss to the community. The need for such a qualification for students from distant lands (Empire as well as foreign) is an additional argument for its institution.

London, E.1. OVERSEAS STUDENT.

TECHNIQUE OF DISCUSSION

SIR,—Some of your readers may like to hear about the conclusions reached at a session of the Sensory Summer School devoted to the subject of democratic discussion. It was agreed that when any committee or other group meets with the aim of reaching agreement on a controversial subject the following improvements on the accepted technique are desirable:

1. That in the initial phase of controversial discussion it is essential to remain receptive to new suggestions and innovations and to treat them from the viewpoint of consolidating and elucidating them before allowing negative criticism, thus enlarging the field of possibly relevant thought.

2. That the method of proceeding by argument around concrete resolutions and their amendments or counter-amendments should be recognised as inefficient and time-wasting. A resolution should be treated as fluid the moment any controversial amendment is proposed, and decision by majority vote should be deferred, if not eliminated, by a readiness to reformulate the subject at issue in terms which may facilitate agreement.

3. That in wording motions it is advisable to avoid both emphatic negatives and positive superlatives which have the effect of ruling out possible alternatives (e.g., phrases such as "The most important point is. . . .").

4. That if opposing sides in a conflict are asked to state all positive elements in their attitude, deadlock may be avoided; or, if deadlock has already been reached, solution may be found by the same method.

5. That every effort should be made to build up a strong tradition of individual self-discipline in discussion, based upon a feeling of responsibility for reaching agreement, keeping in mind at all times the need for positive and relevant statement.

The meeting concluded that any group of people concerned with matters of social organisation or government must, in order to be efficient, both make exact and definite statement of its principles, and at the same time provide methods of continuous self-criticism, developing and re-stating those principles in new terms. A single group rarely, if ever, can fulfil adequately both these functions. An experiment now in progress seems to show that an effective way of doing so is a dual organisation; there should be an executive body dealing with short-term policy and matters of urgency, unhampered by full responsibility for long-term considerations and wider issues, while a sensory body dedicates itself to the deeper implications of truth, principle, and long-term policy. In order to ensure the smooth working of their mutual relationship, the executive should refrain from limiting the scope of the work of the sensory body, and the sensory body should refrain from advising what action should be taken by the executive.

London, W.1. J. N. GLAISTER.

IMMUNISATION AGAINST WHOOPING-COUGH

SIR,—It might be of interest to some of your readers to know that I have seen, in the past twelve months, doing outpatient work at hospital where quite a large number of babies and children have gone through my hands, no cases of whooping-cough. This is attributed in Vancouver to the immunisation against diphtheria and whooping-cough during the period from six months to a year, although of course some children are immunised later. The injections used are made by Connaught Research Laboratories and certainly appear to be highly efficient. When one remembers that the infant mortality for Vancouver varies from 24 to 30 possibly the absence of whooping-cough is a contributing factor.

I thought that your readers would be interested to hear that the absence of whooping-cough is attributed by the pædiatricians to these injections.

DONALD PATERSON
Pædiatrician-in-Charge,
Health Centre for Children.

Vancouver General Hospital,
Vancouver, B.C., Canada.

Public Health

Plumbing in America

AN officer of the Building Research Station has be to study plumbing practice and research in the Unit States, and the Department of Scientific and Industr Research has published a record of his visit.[1]

The "one-pipe" system, in which the waste pi from sanitary fittings of all kinds discharge into a comm pipe directly connected to the drain, is so well establish in America that it has ceased to be the subject of cont versy there. But there are considerable variations its practical application: for example, in two la cities, Philadelphia and Baltimore, special anti-siphon ventilation pipes may be omitted altogether where ea individual waste pipe runs independently to the s waste stack; and elsewhere various degrees of spe ventilation are required.

HAZARDS

Contamination of drinking-water due to cross-c nexions and back-siphonage into water lines has b much attention since the epidemic of amœbic dysent in Chicago in 1933, when 1400 people were ill and died through drinking water contaminated in two la hotels. Investigation has revealed many cases of wa being rendered unsafe after arrival in the plumbing syst of a building, and ill health has often been shown to directly attributable to "pollution in the plumbin In consequence, certain plumbing practices at one ti normal in America have been amended. Speak generally, those found dangerous are:

(*a*) Any cross-connexion between a supply of potable wa and a supply of unpotable water by means of a valve of kind. The more serious cases have arisen where the unpot water was sewage. There have been cases of potable wa supplies being used for flushing drainage pipes by mean a value connecting the water-supply and sewage systems. hazard in any such case of "cross-connexion" is that if valve is opened, or fails to give complete closure, at a ti when the pressure on the polluted water side of the va happens to exceed that on the potable water side, the pota water will become contaminated.

(*b*) Any case where water is supplied to a washing or sanit appliance, or other water-using device, in such a way t the outlet of the supply—e.g., the outlet of a tap or of extension pipe attached thereto—is below the level to wh waste water in the receiving vessel may rise. (In determin this level account must be taken not only of normal us but also of exceptional conditions such as stoppage of overflow channel. Hence the level to be considered is that which water would begin to flood over the top edge of appliance.)

The way in which hazards to health arise in the c of simple cross-connexions has already been noted. T hazard associated with the "submerged" or "und water" inlet, is as follows:

> Negative pressures necessarily occur from time to time the water-supply systems of buildings. For example, if stop valve controlling the supply to a building is closed wh repairs are in progress, any water drawn from the system the house side of the stop valve must come from the wa remaining in the pipes, and as this water falls it induce negative pressure of air in some part of the pipes. If there any submerged inlet it may, by reason of the negative pres in the pipes leading to it, siphon out waste water from t appliances which it serves. For this to happen, the cont tap at the submerged inlet must either be left open or be n completely airtight; but there are many circumstances which taps may be left not completely closed, and cert water-control devices would in any case permit water to p through them in a reverse direction. If the water in t appliance served by the submerged inlet happens to

on producing this valuable booklet so promptly, and at modest price of half a crown. It is a worthy successor to *B.D.H. Guides* of 1914 and 1932.

versity of Aberdeen

On Sept. 29 the following degrees were conferred :

M.D.—E. K. Cruickshank, C. E. Lumsden (with honours); A. McCredie Smith (with commendation).

M.B., Ch.B.—Eric McKay, W. G. Smith (with honours); ne C. Budge, Valerie A. Cowie, A. M. C. Duffus, G. P. ir, Doris I. Manson, M. D. Paterson, Margaret P. B. Reid, G. G. Shepherd (with commendation); R. G. Blues, A. J. Booth, re Bruce, A. R. Burnett, R. F. Cant, G. T. M. Cummins, dy J. A. Davie, A. M. Donaldson, I. McI. Duguid, Leslie bar, A. H. Duncan, G. D. Duncan, John Duthie, H. W. McG. ards, Margaret Farquharson, A. J. B. Gibb, Margaret G. Hay, A. Hendry, Margaret R. Inglis, A. G. Jessamine, A. G. Laing, phine M. Lomax-Simpson, A. H. Lorimer, A. C. MacDonald, A. McIntosh, W. T. D. McKenzie, Ian MacLeod, June M. Taggart, P. T. Main, Doreen Meldrum, Irene Milne, Joan M. , J. C. Mitchell, Douglas Mortimer, T. D. Ness, Norna Pringle, G. Richmond, R. S. Ritchie, J. A. Shanks, Elma M. Simpson, h M. Skea, R. W. Smith, Elizabeth M. Somerville, Helen M. tter, Elizabeth M. Spark, Cecily J. M. Stewart, D. B. Strachan, n R. Struan-Marshall, Audrey Sutherland, James Symonds, beth H. Thom, Margaret H. Thomson, James Wilkie, G. G. mle.

yd Roberts Lecture

On Thursday, Oct. 28, at 4.30 P.M., Mr. R. M. Titmuss will ver this lecture at the Whitworth Street branch of Mary's Hospitals, Manchester. He is to speak on nthood and Social Change.

don Association of the Medical Women's Federation

The annual general meeting of the association will be held the Royal Free Hospital School of Medicine, Hunter eet, W.C.1, on Tuesday, Oct. 12, at 8.15 P.M., with Miss elyn Moore, the president, in the chair. (The ordinary ices have gone astray in the post, and members are refore asked to accept this announcement.)

rnational Congress of Ophthalmology

A list of doctors practising ophthalmology in Great Britain ing compiled for the new Indicia in connexion with this oming congress. All those who are *not* members of the ty of Ophthalmologists or the Ophthalmological Society United Kingdom are asked to send their names, quali- ns, and addresses to the honorary secretary of the , 45, Lincoln's Inn Fields, London, W.C.2.

nal Hospital Boards

Minister of Health has made the following appoint- ts:

th-West Metropolitan.—Dr. W. J. T. Kimber, medical super- dent of Hill End Hospital, St. Albans (in succession to Dr. J. R.).

lsh.—Mr. E. K. Roy Thomas, senior ophthalmic surgeon to Swansea General and Eye Hospital (in succession to Dr. J. Lloyd ies); Mr. J. T. Morrison, dean of the faculty of medicine, versity of Liverpool (in succession to Prof. T. B. Davie). Mr. rison is also a member of the Liverpool Regional Hospital ard.

ffield Medical Fellowships

For the past few years the Nuffield Foundation has offered lowships in child health, industrial health, social medicine, l psychiatry to those who wish to qualify for an academic reer as teachers and research-workers. In all there have en 121 applications and 18 fellowships have been awarded. t their meeting in June the trustees decided that the time d come to widen the scope of the scheme to include all lls of medicine while still giving special consideration to plications for additional training in the four original bjects. Further particulars will be found in our vertisement columns.

dical Protection Society

Dr. A. R. French has been appointed secretary to the society succession to Dr. R. W. Durand, who has resigned to take p the post of superintendent of Belfast City Hospital.

Dr. French was educated at Epsom College and the London Hospital. After taking the Conjoint qualification in 1927 he spent e time in general practice before taking a short-service com- ssion in the medical branch of the Royal Air Force. He then went k into general practice in Greenford until he was called up in ptember, 1939. He served throughout the war and was for some e the officer in charge of the R.A.F. medical statistical office. After his release he studied industrial medicine and took the D.I.H. st year. He has been honorary secretary of the local division l of the Metropolitan Counties branch of the British Medical ociation. He is also a member of the Medico-Legal Society, and he has served with the Pensions Appeal Tribunals.

Royal College of Obstetricians and Gynæcologis

The Dowager Lady Reading, at the annual dinner of the R College of Obstetricians on Oct. 1, paid great tribute to th who specialise in midwifery and the diseases of women. The are moments, she suggested, when they appear as demi gods. In responding, Sir William Gilliatt, the president, told how the list of candidates for membership of the college has grown, from 84 in 1938 to 294 in 1948; and reminded his hearers how the college itself, presented sixteen years ago by Sir William Blair-Bell, had seemed grandiose then, but was now too small for the growing body using it. He referred to the help given by the college in reserving appointments for Dominion postgraduates who come to Great Britain for experience. Last year appointments were reserved for 6 nominated Dominion postgraduates, and additional appointments were found for 9 others who came unexpectedly.

Dr. Emil Novak, president of the American Gynecological Society, replying to Mr. V. B. Green-Armytage who proposed The Guests, was pleasant about any language difficulty which his hearers might experience; indeed, he said, there had been a language difficulty in his own family, for his wife came from Boston, and his son spoke a hybrid tongue. He had that afternoon been made an honorary fellow of the college, to which he brought a gift from the American Gynecological Society—a gavel, made from two door-knobs and a part of a newel-post taken from the house of Ephraim McDowell, the father of ovariotomy. In accepting the gavel on behalf of the college, the president remarked that another fifty years had passed before Spencer Wells did his first ovariotomy in England—though he had subsequently made up for lost time.

Sir Henry Dale, F.R.S., newborn president of the Royal Society of Medicine, claimed leave to suffer from eloquence, the occupational disease of presidents, and described how ergot, and the studies he made of it, had brought him into touch with all sorts of eager minds and famous men; and Prof. Newell W. Philpott, of McGill University, spoke kindly of the help the college had given its friends the Canadian obstetricians and gynæcologists in organising their affairs. He begged for more visits from British gynæcologists.

Middlesex Hospital Medical School

Presiding over a gathering of some 300 people at the annual dinner held in London on Oct. 1, Mr. Maurice Whiting spoke of some of his teachers—John Murray, Sir Gordon Gordon-Taylor, William Lang, and Sir Robert Young. When he entered the hospital in 1907 he was told that patients liked to go to Middlesex because they were treated with care and consideration as well as skill. Such a tradition was worth maintaining. The present position of the medical school was, he felt, largely due to the work of three of its deans, Campbell Thomson, Lord Webb-Johnson, and Dr. Boldero, all of whom had done so much in their several ways. Of a hospital it might be said that the ship was more than the crew, but the ship and crew were one. He hoped that when the Middlesex ship made its voyage into new and uncharted seas the crew would preserve its reputation. Dr. H. E. A. Boldero drew attention to the presence of Prof. Lillian Penson, the first woman vice-chancellor of the University of London and the first woman to attend the Middlesex Hospital dinner. Under the N.H.S. Act, he said, three hospitals had been added to the Middlesex—the Woodside Hospital for Functional Nervous Diseases; the British Red Cross Society's Clinic for Rheumatism, Peto Place (now renamed the Arthur Stanley institute of the Middlesex Hospital); and the Hospital for Women in Soho. He welcomed these hospitals and the great opportunities they brought. Though the medical school now had its separate charter it would remain as closely in touch as before, especially as Colonel J. J. Astor was chairman both of the hospital and of the medical school council. Dr. R. S. C. Couch, as senior Broderip scholar, spoke regretfully of the recent call-up arrangements which would deprive many of his contemporaries of the chance of holding a B2 hospital appointment. Turning to rather lighter topics, he described the invasion of the medical school by women students and seemed to think it might advantageously be carried further. Mr. E. W. Riches concluded the speeches by expressing some of the admiration and affection in which the chairman is held by his colleagues and former students.

Obituary

ALEXANDER WILSON GILL

M.D. EDIN., F.R.C.P.

Dr. Wilson Gill died on Aug. 30, at the age of 60, in the North Staffordshire Royal Infirmary, where till his retirement this year he was in charge of the neurological and cardiological clinics and was senior physician.

He was educated in Edinburgh at the Royal High School and the University, graduating in medicine in 1909. After holding resident appointments at Addenbrooke's Hospital, Cambridge, and the City Infirmary, Birmingham, he obtained his M.D. Edin. in 1912 with a thesis on auricular fibrillation, and then settled in practice in Hanley as the partner of the late Mr. Reginald Alcock. During the 1914–18 war he served in France and Belgium, and when he was wounded showed the courage characteristic of his whole life. With the late Sir Arthur Hurst he became interested in the study of functional diseases in soldiers, and for a year he acted as neurologist at Seale Hayne Military Hospital. He was also assistant editor of the *Seale Hayne Neurological Studies*. On his return to general practice he successfully treated functional disorders by hypnosis.

In 1922 he was elected to the staff of the North Staffordshire Royal Infirmary, and after taking the M.R.C.P. in 1927 he undertook only consultant work. In 1944 he was elected F.R.C.P. His advice was sought particularly on functional as well as organic neurological states and cardiovascular diseases, but he never lost interest in general medicine. A colleague says of him that "he never failed to give comfort to his many patients, both in the lay and medical world. He had a keen understanding and sympathy and imparted confidence with his fluent and explicit diction. There was never a more honourable, upright, and kindly man than Alec Gill, and during his last illness it was often said that he practised what he preached, for he made friends of his fears and faced a difficult situation with fortitude. A great lover of Johnson and Boswell, he spent his spare time either reading the classics or fishing. In his younger days he was a tennis enthusiast."

Mrs. Wilson Gill was formerly Miss Edith Mary Johnson, of Congleton.

Births, Marriages, and Deaths

BIRTHS

CURTOIS.—On Sept. 23, at Singapore, the wife of Lieut.-Colonel G. M. Curtois, R.A.M.C.—a son.

DOCKRAY.—On Sept. 24, the wife of Dr. J. V. Dockray, O.B.E.—a daughter.

HUMPHREY.—On Sept. 25, the wife of Dr. J. H. Humphrey—a daughter.

MARSHALL.—On Sept. 28, at Oxford, the wife of Wing-Commander A. B. Marshall, M.R.C.S.—a daughter.

STIDOLPH.—On Sept. 27, in London, the wife of Mr. Neville Stidolph, F.R.C.S.—a son.

TOBER.—On Sept. 28, in London, the wife of Dr. Archibald Tober—a daughter.

TURNER.—On Oct. 1, in Edinburgh, the wife of Dr. R. D. Turner—a son and a daughter.

WILLIAMS.—On Sept. 26, in London, the wife of Dr. R. E. O. Williams—a daughter.

YORKE.—On Oct. 2, in London, the wife of Dr. Allan Yorke—a son.

MARRIAGES

FRANCIS—WARREN.—On Sept. 9, at Bromley, Arthur Evans Francis, M.D., to Maria

INGRAM—FORBES, at Montana, Switzerland, George Ilsley Charlton Ingram, M.B., to Patricia Margaret Forbes Irving.

McKENZIE—BUCK.—On Sept. 30, at Birchington, James Alexander McKenzie, M.B., to Joyce Isabel Buck.

MAILE—KELLY.—On Sept. 25, in London, William Burgess Drayson Maile, M.D., to Mary Sheila Bridget Kelly.

PRITCHARD—LEE.—On Sept. 25, in London, John Pritchard, M.R.C.S., to June K. Lee.

WYPER—VERITY.—On Sept. 22, in Edinburgh, John F. B. Wyper, M.B., to Margaret Janet Verity.

DEATHS

AUBREY.—On Sept. 30, Harold Percival Aubrey, M.R.C.S., aged 66.

COSGRAVE.—On Sept. 30, Frederick Robert Cosgrave, M.D. Dubl.

NASH.—On Sept. 29, at Ashwell, Herts, Lorimer Gifford Nash, M.R.C.S.

SASS.—On Sept. 30, at Deal, Frederick Joseph Wilfrid Sass, M.R.C.S., D.P.H.

Notes and News

UNIVERSITY STIPENDS

LAST week Prof. C. E. Raven, D.D., in his address to t senate at the beginning of his second year as vice-chancell of Cambridge University, discussed the growing discrepan between the incomes which could be earned in the universiti and in other professions. The University Grants Committ had lately pointed out that the maximum professorial sala which the Treasury recognises is £1450. If there was to any ladder of promotion this meant that junior posts wou hardly carry a living wage—certainly not a wage on whi to marry and bring up a family. After six years of natio service, men who held fellowships or junior teaching po were being paid at the age of 30 salaries hardly larger th those offered in 1939 to men of 23. And these discrepanc would be aggravated, he pointed out, when the findings of t latest Spens report were implemented. For instance, t stipends of Cambridge professors did not rise above £15 but a specialist appointed to the staff of a hospital was to guaranteed a salary rising to £2500 at the 1939 value of mon "If the salaries of our own teachers of medicine are to raised to the figures specified in the report," Dr. Rav continued, "we shall have anomalies in the scientific depa ments of the university which will not only be absurd b intolerable. It seems obvious that the University Gra Committee will have to reconsider the decision which has at present upheld; or else we shall have to qualify the medical school."

A SCOTTISH HOSPITAL

Dr. Gibson, the present medical superintendent, tells t story of the Dundee Royal Infirmary[1] from its lowly ori as a local dispensary about 150 years ago, describing development into one of the finest institutions of its ki Like all human institutions, it has had its vicissitudes; b it has always commanded the help of able and willing m and women. All classes of the community have contribut something to this, and some of Scotland's most distinguis physicians and surgeons have served on its staff. In Gibson the hospital has found a biographer as interest as he is devoted.

VITRELLÆ

THE joint committee of the British Medical Association of the Pharmaceutical Society of Great Britain which been compiling a *National Formulary* has been seeking convenient name for that group of therapeutic agents wh are inhaled after crushing a small glass capsule. To disting these preparations from the "inhalations," and from capsules intended to be swallowed, which form distinctive quite different groups, the word "vitrella" has been cho as being both precise and descriptive. It is proposed to u this title for this class of preparation in the formulary. Befo long, therefore, we shall be ordering "Vitrella amylis nitri min. 3."

THE B.P. 1948 EXPLAINED

A NEW pharmacopœia is scrutinised as carefully as t results of a general election—and the emotional accompa ments are not dissimilar. In the *B.P. 1948* new drugs a preparations are conveniently tabulated; and there are li of those which have been relegated to another place (oft the *B.P.C.*). But there is never a word about pharmacologic actions—a double misfortune for readers unfamiliar with ne official names, even though the compounds may be old frien in new guise. Discussion of the actions of drugs is still le to the writers of textbooks of pharmacology. In these difficu days, however, publishers of textbooks can rarely synchroni the release of new editions with the appearance of a new *B.F* even if authors would always coöperate. *The B.D.H. Gui to the B.P. 1948* is therefore particularly welcome. Fro this slender volume (pp. 145 + xiv) containing notes on th official monographs arranged alphabetically, the doctor pharmacist can see at a glance whether a preparation is a old one, wholly or to all intents unchanged: an old on altered in strength or composition (*); or a new on altogether (**). When necessary a few words are added o pharmacological actions, and drugs which come under th D.D.A. or regulations or on the poison schedules are clearl indicated. The British Drug Houses Ltd. are to be congratu

STREPTOMYCIN THERAPY OF TUBERCULOUS MENINGITIS IN CHILDREN

K. CHOREMIS
M.D. Athens
PROFESSOR OF PÆDIATRICS AND DIRECTOR OF PÆDIATRIC CLINIC, UNIVERSITY OF ATHENS

N. ZERVOS
M.D. Pisa
ASSOCIATE PROFESSOR OF PÆDIATRICS TO THE CLINIC

V. CONSTANTINIDES
M.D. Athens
SENIOR ASSISTANT PHYSICIAN

S. PANTAZIS
M.D. Athens
CHIEF OF BACTERIOLOGY DIVISION OF THE CLINIC

FROM April 1 to Nov. 30, 1947, 72 cases of tuberculous meningitis were treated in the Pædiatric Clinic of the University of Athens. Of these cases 13 began as miliary tuberculosis and 59 as a severe primary infection with, in some cases, a perifocal spread. Thoracic spondylitis was present in 3 cases, and 1 case was a sequel to cervical adenitis.

In 9 cases no streptomycin was given and death ensued. Streptomycin was given to the remaining 63 patients (tables I and II). Combined intramuscular and intrathecal therapy was applied routinely, and intrathecal therapy was regarded as indispensable. Of these 63 patients, 34 died and 29 survived. In almost all our fatal cases necropsy was refused.

Enough patients have survived for a sufficient period to allow us to observe phases of tuberculous meningitis which in pre-streptomycin days were very brief or, in most cases, never seen. We feel that the full potentialities of streptomycin will not be disclosed until the dosage, method of administration, and duration of treatment are correlated with the clinical and biological progress of the disease.

Four factors must be considered together in planning the attack with streptomycin and in managing the course of treatment: the antibacterial power of streptomycin; the acquired resistance of *Myco. tuberculosis* to streptomycin; the toxic effects of streptomycin; and the stage of the disease at which treatment is begun. Our investigations have been directed towards elucidating the relationship between the third and fourth factors and the progress of the tuberculosis, for here, we believe, lies the secret of the best use of streptomycin.

We are not impressed with the significance of the presence of *Myco. tuberculosis* in the cerebrospinal fluid (C.S.F.). We have evidence, both from our own experience and from that of others, that the finding of this bacillus in the C.S.F. is not inevitably followed by tuberculous meningitis. We lately reported [1] cases of meningism, with *Myco. tuberculosis* in the C.S.F., associated with primary tuberculosis in children, where no meningitis developed and with no specific treatment the children recovered in a few days. We have also recently discharged patients who have had tuberculous meningitis treated with streptomycin and whose clinical condition and C.S.F. findings have become normal except for the continued presence of *Myco. tuberculosis* in the C.S.F. After varying periods there has been no relapse in these cases and certainly there has been no immediate recurrence of the meningitis.

DOSAGE

Opinions vary considerably about the dosage of streptomycin in tuberculous meningitis. At first we gave 2 g. of streptomycin daily, but later we reduced the dose to 1 g. daily or even less. The optimum dosage depends on the patient's age and on the stage of the disease. Both intramuscular and intrathecal administration were used (tables I and II), and we are now satisfied that the more severe the signs the smaller should be the intrathecal dose. Thus, to an infant with advanced tuberculosis we would give 0·5–0·6 g. daily, of which 0·05 g. would be intrathecal and the rest intramuscular. The intrathecal dose may even be less than 0·05 g. —sometimes as little as 0·01 g.

DURATION OF TREATMENT

Here again there is great difficulty, but in our experience three or four months is the average period during which streptomycin will exert its main therapeutic effect. We combine continuous and intermittent administration to put off for as long as possible the acquisition of tolerance of streptomycin by the bacillus and to avoid the unwelcome effects of protracted intrathecal injection.

In general we give about four to six weeks' initial treatment, both intrathecally and intramuscularly. We usually find a well-marked amelioration of signs and symptoms at the end of this, but laboratory reports show that tuberculosis is still present. We call this the *period of clinical improvement.*

We next discontinue treatment for five to ten days, after which we resume treatment for ten to fifteen days. There follows a further rest period and then further treatment as before, and this phase of intermittent treatment may go on for as long as three months. Our treatment in this phase depends on the laboratory findings, for as a rule the patients by now show no evidence of meningitis. We call this stage the *stage of laboratory restitution.*

We agree with other observers that, after the first and acute stage is over, the patient's clinical appearance is no indication for stopping treatment. Further, while the cell-count and biochemical findings show that the C.S.F. is still abnormal, the probability, perhaps even certainty, is that the child will have an exacerbation. Therefore, while the C.S.F. findings show any signs of tuberculous meningitis the treatment must go on.

METHODS OF ADMINISTRATION

It is known that streptomycin has a local effect. We have seen immediate regression in cases of adenitis and fistulæ under local streptomycin therapy. Nevertheless, some workers have queried the desirability of intrathecal administration and have used only the intramuscular route. The irritant effects of streptomycin on the theca have been confirmed by our experience. Intrathecal streptomycin leads to an increase in the amount, the cell-count, and the albumin content of the C.S.F., and a long series of intrathecal injections may cause complete obstruction of the spinal canal.

Advanced tuberculous meningitis always produces an acute hydrocephalus, and the paralytic stage follows. Therefore, in view of the known tendency of intrathecal streptomycin to irritate and bring about blockage of the cerebrospinal canal, the risk of aggravating a natural tendency of the meningitis should be kept in mind. At the start of our experiments, when large doses (0.1 g. or more) were given, we have seen an aggravation of meningitis, including hydrocephalus, under the influence of intrathecal streptomycin, and death has been accelerated in this way.

Yet we believe, with others, that intrathecal therapy is indispensable in the treatment of tuberculous meningitis. We tested the intrathecal action of streptomycin on three physically healthy children, with the results shown in table III. In other cases we have noted that continuous intrathecal injection leads to blockage of the flow of C.S.F. to the point of occlusion and dry puncture. We can only regard this as the result of injury to, and irritation of, the meninges; in fact a necropsy showed a local traumatic adhesive meningitis completely interrupting the flow of C.S.F. Since we began intermittent treatment we have not observed any blockage at all.

---

Society of Medical Officers of Health

At a meeting of the society to be held on Thursday, Oct. 14, at B.M.A. House, Tavistock Square, W.C.1, at 5.40 P.M., Prof. R. H. Parry will be installed as president and will deliver his presidential address.

Royal London Homœopathic Hospital

The King, who is patron of the London Homœopathic Hospital, has commanded that in future it shall be known as the Royal London Homœopathic Hospital. The hospital will celebrate its centenary next year.

St. John's Hospital Dermatological Society

Dr. J. M. H. MacLeod will deliver the Prosser White oration at 1, Wimpole Street, London, W.1, on Thursday, Oct. 28, at 4.30 P.M. The title of his address is Milestones on a Dermatological Journey. A dinner will be held the same evening. Further particulars may be had from the secretary of the society, St. John's Hospital, 5, Lisle Street, W.C.2.

Royal Institute of Philosophy

In the Michaelmas term a course of lectures on Foundations of the Moral Life will be given at the institute, 14, Gordon Square, London, W.C.1, on Fridays at 5.15 P.M., beginning on Oct. 15. Cards of admission may be had from the director of studies at the institute. Viscount Samuel will deliver his presidential address at 5.30 P.M. on Oct. 20. He is to speak on the Decline or Revival of Religion.

British Association of Plastic Surgeons

The clinical congress held by the association, under the presidency of Prof. T. P. Kilner, at Oxford and Stoke Mandeville from Sept. 16 to 18 was attended by 91 plastic surgeons, including visitors from America, Sweden, Norway, Belgium, Ireland, Denmark, and South America. The guest of honour was Dr. Sumner L. Koch, of Chicago, who gave an address on Surgery of the Hand.

Proper Use of the Health Service

Mr. Aneurin Bevan, Minister of Health, addressing the British Hospitals Contributory Schemes Association on Oct 1, said that the National Health Service would fail unless the people used it intelligently, sparingly, and prudently. As reported in the *Times*, he added: "There is as much need for prudence on the part of the profession in giving the benefits of the service as there is for the population in the claiming of those benefits."

King's College Hospital Medical School

The annual dinner was held in London on Oct. 2, after the formal opening of the medical school on the previous day. Prof. Henry Cohen, who had delivered the oration at the opening ceremony, was the guest of honour, and emphasised that though the increasing number of committees these days was a heavy burden to bear it was important that the responsibility should be accepted, for that was the only means whereby *medical men might influence their future.* Mr. Harold Edwards, the dean, pointed out that the changing needs of today necessitated considerable modification of the curriculum. Among other guests who attended were the non-medical members of the recently constituted council of the medical school, including the Marquis of Normanby, the new chairman of the hospital.

Award for Gallantry

The King has awarded the Albert Medal to Dr. A. R. C. Butson, a member of the Falkland Islands Dependencies Survey, in recognition of his gallantry in the following circumstances:

> On the evening of July 26, 1947, an American member of the Ronne Antarctic Research Expedition fell into a crevasse some 6 miles from base. Two teams were sent to the rescue, but the hazards of crossing a heavily crevassed glacier were much increased by darkness, and it was not until 4 o'clock on the morning of July 27 that the crevasse into which the American had fallen was located. Butson immediately volunteered to be lowered into the crevasse where he found the American tightly wedged 100 ft. down and suffering from shock and exhaustion. For nearly an hour he had to chip the ice away in an extremely confined space in order to free the American, who was brought to the surface and placed inside a tent. Butson then rendered the necessary medical aid and at dawn a return to base was made carrying the American on one of the sledges.

Dr. Butson, who is a Cambridge graduate, qualified from University College Hospital in 1945.

Appointments

DONOVAN, G. E., M.D., M.SC. N.U.I., D.P.H.: divisional M.O., W Glamorgan.
DURAND, R. W., M.R.C.S.: superintendent, Belfast City Hospit
HOLME, THOMAS, M.B. Manc., D.P.H.: divisional M.O.H., Stalybrid and Dukinfield, Cheshire.
TAYLOR, G. H., M.D. Lond., D.P.H.: deputy county M.O.H. a deputy school M.O., Warwickshire.

Fulham Hospital:
COMERFORD, R. E. W. B., M.A., M.B. Camb., D.A.: senior resid anæsthetist.
MCSWEENEY, TERENCE, M.B. N.U.I.: casualty officer.
WALLACE, D. M., O.B.E., M.S. Lond., F.R.C.S.: part-time regist. to genito-urinary department.

University of Wales:
Asst. M.O. for student welfare:
GRANT, GRAHAM, M.B. Lond.
WILLIAMS, LILIAS, M.B. Edin., D.P.H.

Diary of the Week

OCT. 10 TO 16

Monday, 11th

ROYAL COLLEGE OF SURGEONS, Lincoln's Inn Fields, W.C.2
5 P.M. Mr. F. S. Cooksey: Rehabilitation and Surgery.
MEDICAL SOCIETY OF LONDON, 11, Chandos Street, W.1
8 P.M. Annual general meeting.
8.30 P.M. Dr. T. Jenner Hoskin: Thyrotoxicosis. (Presiden address.)

Tuesday, 12th

ROYAL COLLEGE OF PHYSICIANS, Pall Mall East, S.W.1
5 P.M. Dr. Desmond Curran: Prefrontal Leucotomy. (F Croonian lecture.)
ROYAL COLLEGE OF SURGEONS
5 P.M. Mr. R. C. Brock: Surgery of the Heart and Gi Vessels.
INSTITUTE OF DERMATOLOGY, 5, Lisle Street, W.C.2
5 P.M. Dr. I. Muende: Histology of the Skin.
CHELSEA CLINICAL SOCIETY
7.30 P.M. (South Kensington Hotel, 47, Queen's Gate Terr S.W.7.) Dr. Geoffrey Evans: Empiricism in Medici

Wednesday, 13th

ROYAL COLLEGE OF SURGEONS
5 P.M. Prof. J. R. Learmonth: Pathological Physiology Peripheral Arterial Disease.
ROYAL INSTITUTE OF PUBLIC HEALTH AND HYGIENE, 28, Port Place, W.1
3.30 P.M. Dr. W. G. Wyllie: Weaning and Mixed Feeding of Infant.
INSTITUTE OF LARYNGOLOGY AND OTOLOGY, 330, Gray's Inn R W.C.1
10 A.M. Mr. J. D. McLaggan: Treatment of Cardiospasm.
UNIVERSITY OF GLASGOW
8 P.M. (Department of Ophthalmology.) Dr. Paul Baci Experimental Corneal Grafting.

Thursday, 14th

ROYAL COLLEGE OF PHYSICIANS
5 P.M. Dr. Curran: Prefrontal Leucotomy. (Last Croon lecture.)
ROYAL COLLEGE OF SURGEONS
5 P.M. Mr. Denis Browne: Surgery of Congenital Deformi of the Extremities.
BRITISH INSTITUTE OF RADIOLOGY, 32, Welbeck Street, W.1
8 P.M. Sir Stanford Cade, Dr. J. L. Dobbie, Mr. W. D. Harm Carcinoma of the Buccal Cavity.
INSTITUTE OF DERMATOLOGY
5 P.M. Dr. H. J. Wallace: Erythematosquamous Eruptions
SOCIALIST MEDICAL ASSOCIATION
7.30 P.M. *North West Middlesex Branch.* (Town Hall, Wemble Dr. E. H. Capel: An Industrial Health Service.

Friday, 15th

ROYAL COLLEGE OF SURGEONS
5 P.M. Mr. T. Holmes Sellors: Surgery of Pulmona Tuberculosis.
FACULTY OF RADIOLOGISTS
2.15 P.M. *Therapy Section.* (Royal College of Surgeons.) Mr. A. Durden Smith, Dr. J. R. Nuttall, Mr. G. W. Blomfiel Palliative Treatment in Advanced Breast Cancer.

Mr. Aneurin Bevan, the Minister of Health, has appoint Mr. J. E. Beddoe to be his principal private secretary.

On Oct. 15 Dr. J. F. Brailsford will reach New York begin a lecture tour in the United States during which he w address the Annual Meeting of Radiologists at San Francisc

CORRIGENDA.—*Exchange Transfusion in Hæmoly Disease of the Newborn* (Oct. 2, p. 522). Dr. Mollison co-author is Miss Marie Cutbush, B.SC.

In our note last week on Dr. J. V. Dacie's appointme as reader in hæmatology at the Postgraduate Medic School of London, the word *hæmostatic* should have be *hæmolytic*.

and respiratory disturbances going on perhaps to Cheyne-Stokes breathing; the persistence of any of these is an indication for the absolute cessation of streptomycin therapy; cisternal puncture is the only useful palliative measure. If the signs improve, small daily intrathecal doses (beginning, say, with 0·01 g.) may be started and slowly increased, so long as none of the above signs and symptoms recurs. It may be necessary to keep the dose minimal for many days, but we have observed that, when the crisis has safely passed, the intrathecal dose can be increased from 0·01 to 0·1 g.

Large Intrathecal Daily Doses in Early Cases.—The more advanced the meningitis the greater the reaction to intrathecal streptomycin, and a patient admitted with no irritative symptoms can tolerate relatively larger doses. The rationale of large early intrathecal doses is to combat the bacilli when the symptoms and signs are relatively slight and the meningeal irritation is not well marked, with no evidence of hydrocephalus or paralytic phenomena. As the clinical picture improves, the doses may be decreased gradually until they can be abandoned in favour of intramuscular therapy alone. There is a very definite risk that intrathecal streptomycin will aid the production of hydrocephalus. In early cases this risk must be taken, but the nearer one gets to the hydrocephalic stage the more care is necessary with intrathecal therapy.

RESULTS

Tuberculous Meningitis

Of the 50 patients treated 21 have been discharged cured according to clinical and laboratory findings, 3 are still under treatment and show clinical improvement with significant laboratory findings, and 26 have died (tables I and II).

In most of the 21 cases cured. treatment was begun in the first ten days of disease. Two broad phases can be described: (1) clinical improvement; and (2) recovery confirmed by C.S.F. laboratory findings. During clinical improvement intensive intrathecal and intramuscular treatment was given with the immediate aim of arresting the disease, and relatively large doses were administered. This phase lasted, on an average, four or five weeks, and by that time the clinical picture had become normal and gave a favourable prognosis. The phase of recovery ranged two or three months, during which we still gave both intramuscular and intrathecal streptomycin but in smaller doses, the intramuscular dose being much larger than the intrathecal, which was steadily reduced. During this phase intermittent treatment was continued until the C.S.F. had become almost normal (albumin 0·3 g. per 100 g., and cells fewer than 10 per c.mm.). The periods of "rest" were gradually lengthened. After this, further treatment for a month by the intramuscular route was given and then the patient was discharged. The patient remained under weekly observation and after three months was given ten days' intramuscular therapy, repeated at three-monthly intervals during the first year. Some of these cases have been under treatment and observation for about a year now (table I), and in none of them has any sign of relapse been seen, and they are perfectly well.

The 3 patients in whom the laboratory findings have not confirmed what appears to be a clinical cure (table I) are still under treatment.

Of the 26 patients who died (table II), 3 had received what might be called a full course of treatment—i.e., long enough for a favourable effect to show itself if it was going to appear at all—and 23 died before they had received a full course of treatment. In every one of this group the history suggests that the disease had lasted at least fifteen days before the child was given intrathecal streptomycin. Table II shows that streptomycin clearly prolonged the disease in 7 cases and possibly in more, and its clinical course was changed from that which we have seen so many hundreds of times in pre-streptomycin days.

Note relatively few deaths in those who survived more than a few days.

"Complete" treatment refers to cases which had a substantial amount of streptomycin which in other cases has produced a cure, whereas those given "incomplete" treatment died before a possibly curative dosage could be completed.

Some 14 of these children died within a week of admission to hospital. Among them the signs of hydrocephalus were slight and the rise of tension of the C.S.F. was not well marked. No true opisthotonos developed. In the final stages the temperature and pulse-rate rose suddenly, the temperature rising higher and more quickly than the pulse-rate, so that the pulse line crossed the temperature line on the chart, a phenomenon often noted by Continental workers.

On the other hand, where treatment had been lengthy, death was a direct result of excessive intracerebral tension due to acute hydrocephalus. The evolution of tuberculous meningitis to this stage is undoubtedly due to the prolongation of the disease by streptomycin.

We cannot explain the failure of streptomycin in this group, but delay in starting treatment certainly limits its favourable effects and makes administration more hazardous. For reasons mentioned above, intrathecal streptomycin given at the wrong time, in advanced stages of tuberculous meningitis, may accelerate the end and possibly be the actual cause of death.

A few of the children had been treated before admission with intramuscular streptomycin for three weeks or more. None of these recovered, and we believe that intramuscular streptomycin does nothing towards preventing

Streptomycin modifies the classical picture of tuberculous meningitis in its two stages, inflammatory and hydrocephalic, and by prolonging the patient's life increases the incidence of extreme hydrocephalus with fontanelles and even cranial sutures widely open. It is a weakness of the treatment that streptomycin contributes to this effect both directly and indirectly by lengthening the disease. In our earlier cases our persistence with large intrathecal doses undoubtedly contributed to a fatal issue.

We no longer see deaths in the paralytic state as w did before the introduction of streptomycin, but there ar many more deaths from acute hydrocephalus. The sign which should be carefully watched for in streptomyci treatment are gradually increasing opisthotonos, repeate uncontrollable vomiting, a sudden increase in pulse-rate

* Tuberculous spondylitis.

admitted with a positive Mantoux and end fatally the positive reaction persists throughout.

Erythrocyte-sedimentation Rates (*E.S.R.*).—These do not help very much. They are so irregular that one cannot draw conclusions from them. The rate is often high at the start of treatment and low when much improvement has taken place.

Lipase in C.S.F.—We do not know of other investigations into the variations of the lipase content of the C.S.F., and our conclusions are submitted with reserve. We use the Comfort-Osterberg method of evaluation, and we note that the lipase content seems to be lower in advanced stages of tuberculosis during the primary phase of therapy. It becomes even lower but rises again as soon as the patient's condition has definitely improved.

Sugar and Chlorides in C.S.F.—Diminution and irregular variations of the sugar and chlorides are noted initially, but as improvement takes place their quantities increase and tend to remain within normal limits.

SECONDARY EFFECTS AND TOXICITY

We are satisfied that vertigo, headache, and vomiting [illegible] due to streptomycin, but these symptoms do not persist. We believe also that the ocular phenomena which have been described are mainly due to the tuberculosis and tend to disappear under streptomycin therapy. We wish to draw special attention to alterations in the fundus. Of the 21 patients discharged as cured a baby aged 6 months presented with a partial atrophy of the papilla, which was cured after four months' treatment. A second showed atrophy of the papilla and cerebellar disturbances. Both of these cases were given relatively large doses of streptomycin. Another case developed [illegible] well-marked hypertrichosis on the front of the leg which later regressed. One patient showed mental confusion and logorrhœa which, though diminishing, [illegible] persist. Another presented the same symptoms which cleared quickly. In 2 patients paresis of the left [illegible] was seen, and both are improving. One case only [illegible] permanent disturbance of the eighth nerve. We [illegible] not observed any toxic effects other than these.

AUXILIARY THERAPY

We have used tuberculin in all our cases, except [illegible] which proved fatal soon after admission. We thought to reinforce the effects of streptomycin, having [illegible] led to the conclusion that streptomycin modifies [illegible] tuberculin reaction and, we think, intensifies it. We feel too that, under streptomycin, the margin between [illegible] toxic and therapeutic doses of tuberculin becomes [illegible]er. We do not know whether the very small doses [illegible] streptomycin we use have anything to do with this, and we do no more than report the fact. We have, however, divided a later series of cases and are treating [illegible] of them with streptomycin and tuberculin and half without tuberculin.

We have in certain cases, where the general condition was very poor, given blood-transfusions with temporary relief and a gain of time, and we have also given each patient concentrated vitamins A and D.

SUMMARY

Streptomycin therapy was given to 63 children with tuberculous meningitis, 13 of whom also had miliary tuberculosis.

Cures, according to both clinical and laboratory findings, can be obtained with combined intramuscular and intrathecal injections of streptomycin, recovery being accompanied by a high degree of allergy.

Early treatment with streptomycin is of prime importance—the earlier the treatment the more favourable the prognosis. By "early" is meant within the first ten days from the onset. This does not mean that the apparently hopelessly ill patient cannot be cured; nor that every early case can be cured.

In cases which do not respond to streptomycin a streptomycin-resistant strain of *Myco. tuberculosis* is probably present, but we have no laboratory confirmation of this.

Undesirable effects seem to be more the result of the disease in advanced stages than of the streptomycin in the doses we have come to use.

Dosage depends on the time when treatment is begun in relation to the stage of the disease, and to a less extent on the patient's age. Very young children usually need and tolerate streptomycin in larger doses per unit of body-weight than do older ones. Our dosage is the smallest so far recorded. Tuberculous meningitis combined with miliary tuberculosis needs larger doses and longer treatment than meningitis alone.

Our best results have been with intermittent treatment with intervals of rest.

We believe that paratracheal adenitis in primary tuberculosis is too often a forerunner of tuberculous meningitis for this to be regarded as coincidental, and we consider that streptomycin should be used in the treatment of severe cases of primary tuberculosis in children. Of 18 such patients 12 subsequently developed tuberculous meningitis.

We are unable to give an opinion on the danger of creating streptomycin-resistant strains of *Myco. tuberculosis*.

Intrathecal streptomycin is essential in tuberculous meningitis. The intrathecal dosage should be kept to the effective minimum. The effect of the drug must be watched all the time, and wrong dosage will add an unfavourable element to the progress of the disease.

We express our deep gratitude to Dr. J. M. Vine, chief of the Greece Mission of the World Health Organisation, for help in translating our observations into English and for his collaboration in the discussion of our work.

RECURRENT DISLOCATION OF THE SHOULDER

THE SURGICAL TREATMENT

J. E. RICHARDSON
M.S. Lond., F.R.C.S.
LATE SURGICAL FIRST ASSISTANT AND REGISTRAR,
LONDON HOSPITAL

THE anatomical and physiological causes of recurrent dislocation of the shoulder may be summarised as a deficiency in the anterior part of the capsule, due to either stretching or rupture, with a weakness of the spinati muscles, allowing the intact subscapularis muscle to pull the head of the humerus forwards out of a normally shallow glenoid cavity. The importance of the bone lesions appears to be secondary in that they are probably the result rather than the cause of the dislocation. If, however, there is any congenital deficiency in front of the glenoid cavity or behind the humerus, this will strongly predispose the shoulder-joint to recurrent dislocations.

Based on these structural and functional changes, the rational treatment to prevent further dislocation is to repair the capsule, restore the muscular balance, and increase the area of the articular surfaces. In any operation, however, the possibility of producing adhesions must be considered. These adhesions can be either extra-articular or intra-articular. The extra-articular adhesions will be situated in the operation wound; since the approach is usually anterior, the adhesions will be mainly in front of the joint. Intra-articular adhesions are much more important. In any procedure in which the shoulder-joint is opened a hæmarthrosis is likely, since no tourniquet can be applied above the site of the operation, and it is impossible to apply any firm bandage to control the reactionary hæmorrhage.

TABLE III—EFFECTS OF INTRATHECAL INJECTIONS OF STREPTOMYCIN IN HEALTHY CHILDREN

Child	Age (yr.)	Daily intrathecal dose (g.)	Cerebrospinal fluid						Remarks
			Albumin (g. per 100 ml.)		Cells (per c.mm.)		Sugar (Benedict) (mg. per 100 ml.)	Chlorides (g. per 100 ml.), as sodium chloride	
			Before injection	24 hr. after injection	Before injection	24 hr. after injection			
A	4	0·15	0·02	0 15	2–3 lymphs	1800 polys	..	..	Rise of temperature from 98·4 to 103°F a injection; convulsions and vomiti Only one injection given
B	3½	0·05	0·025	0·04	2–4 lymphs	340 polys	40–50	0 7–1·0	These injections were continued for six d After two more days lumbar C.S.F. c tained albumin 0·035 g. per 100 while cisterna fluid contained albu 0·025 g. per 100 ml., and lumbar cell-co was 170 per c.mm. against cisternal co of 65 per c.mm. There was no change either sugar or chlorides
C	3	0·05	0·02	0·03	3–4 lymphs	222 polys	40–50	0·7	Treatment given for six days and stopped. Two days later lumbar C. contained albumin 0·03 g. per 100 while cisternal fluid contained albu 0·02 g. per 100 ml. and lumbar cell-cou was 108 per c.mm., while cisternal co was 30 per c.mm. with 75% polymorp In this case, before treatment, b lumbar and cisterna punctures were d and showed the same amount of albu and cells in each. There was no change either sugar or chlorides in this case

hydrocephalus and the increased tension, and that when we started intrathecal treatment we probably did more harm than good.

Death took place more often among the very young than among older children. The average age of the 21 patients who recovered was 6 years 11 months, whereas that of the 26 who died was 4 years 8 months. The difficulty of early diagnosis in infants, plus the association of the meningitis with primary tuberculosis in so many cases, contributes to this. Moreover, the antigenic resistance in infants is lower than in older children. We also found miliary tuberculosis more often in the very young, and some of our patients had tuberculous bronchopneumonia.

Miliary Tuberculosis with Tuberculous Meningitis

Of 13 cases in this group (tables I and II), 2 seem to have been cured, according to clinical, radiological, and laboratory standards, some twelve months after admission; 2 were discharged with clear clinical, radiological, and laboratory findings, but have relapsed with meningitis twelve months after admission and six months after the end of treatment in the one case, and eight and a half months after admission and three months after the end of treatment in the other. One child has improved —i.e., the clinical condition is good but the laboratory findings are abnormal—and is still under treatment after six months; and the other 8 children died—3 after lengthy treatment, and 5 before a full course of streptomycin could be completed.

The relatively small number of patients with miliary tuberculosis who are either admitted with tuberculous meningitis or develop it later (in this series 13 out of 66, and in an earlier pre-streptomycin series about 10 in 100) makes us wonder what, if any, is the connexion between the two conditions. The treatment of miliary tuberculosis with streptomycin has not prevented tuberculous meningitis arising as a complication under a somewhat disguised clinical aspect. (We have never known miliary tuberculosis to follow tuberculous meningitis.) Since December, 1947, however, 8 cases of miliary tuberculosis treated with streptomycin have not shown any meningitis. We have seen so many cases of primary tuberculosis in children up to 2 years of age, with enlargement of the paratracheal glands (as opposed to the hilar group), go on directly to tuberculous meningitis that we feel that this is more than a chance happening. Of children with tuberculous paratracheal adenitis in pr streptomycin days 12 died of tuberculous meningit within six months of the first diagnosis of glandul tuberculosis.

The development of meningitis cannot be exclud even when a case of miliary tuberculosis seems to be doi well under streptomycin. In miliary cases that devel meningitis the method of administration is the same for uncomplicated tuberculous meningitis. The cou of the disease is longer, and prognosis is difficult, with t age of the patient as an important factor. Milia tuberculosis with tuberculous meningitis in infants the most severe and intractable form of tuberculos which we have submitted to streptomycin therapy. W perform regular spinal puncture in all cases of miliar tuberculosis in an effort to obtain early information abo asymptomatic or camouflaged meningitis. The progno when a patient is admitted with both forms is ba but it seems to be better when a patient with milia tuberculosis develops meningitis after some treatme with streptomycin.

INFLUENCE OF STREPTOMYCIN THERAPY ON MANTOU REACTION, E.S.R., AND C.S.F. FINDINGS

Mantoux Reaction.—We use Koch O.T. 1/10,000 o the flexor aspect of the wrist or on the inner thigh. W read the result after twenty-four hours, and measure t reaction by the method of Groer. The test is repeate every fifteen days during treatment. In cases admitte in an advanced stage the Mantoux is negative. Bu as treatment goes on and improvement begins the reactio becomes positive and more strongly so as improvemen continues. In cases not so severe on admission we fin the reaction strongly positive during the initial phases o treatment, decreasing and remaining at a lower leve and finally rising again as the tuberculosis definitel regresses. The reaction has remained strongly positiv in all children who have been discharged and report bac for control. When charted according to the Groer scheme the reaction shows three stages: (1) the acute, with high curve to the end of the period of clinical improve ment; (2) the sustained, with a lower curve whic continues until the following stage; and (3) the con valescent, or perhaps recovered, stage where the curv again becomes high. In advanced cases which ar low-up a year or two later a full range of movement was found in 14 shoulders, a limited range in 1 (patient was not traced), and in 12 shoulders there been no recurrence of dislocation.

SUMMARY

Recurrent dislocations of the shoulder-joint are due a combination of structural and functional circum- which should be considered in the planning of operation.

Restoration of the normal synergistic action of the muscles by partial tenotomy of the subscapularis muscle, bined with an artificial increase of the articular area the glenoid cavity, should give the highest percentage cures with the normal range of movement.

An operation of this kind is described, and the results 14 cases are tabulated.

wish to thank Prof. T. P. McMurray who showed me, was using, a similar principle in operating, and the ical Director-General of the Royal Navy for permission ublish these cases.

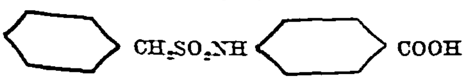
rapid excretion of penicillin by the kidneys has it difficult to maintain constant therapeutic -penicillin levels. Attempts to do so have been in different ways—e.g., by giving frequent intralar injections, by using oily media to delay the ption of penicillin (Romansky and Rittman 1944), by trying to delay the excretion of penicillin by the tubules.

me 80% of the penicillin which appears in the urine been excreted by the tubules (Rake and Richardson), and its excretion by this route can be delayed by done (Rammelkamp and Bradley 1943), *p*-aminopuric acid (Beyer et al. 1947), or sodium benzoate aulding et al. 1947). Beyer (1947) suggests that these ances functionally saturate the renal tubules and inhibit the elimination of penicillin. Their application to therapeutics is limited, however, because they are eted as rapidly as penicillin, and hence it is only sible to maintain adequate concentrations by their tinuous intravenous administration.

Beyer (1947) has reported that the tubular excretion penicillin can be reversibly inhibited by the administion of a compound synthesised by Sprague et al. Beyer et al. 1947) and marketed in this country r the trade name of 'Caronamide':



Caronamide
(4'carboxyphenylmethanesulphonanilide)

t was claimed that, though this compound could block tubular excretory mechanism for penicillin, it was minated from the body by slow glomerular filtration. t was absorbed from the alimentary tract and could be given by mouth in sufficient quantities to produce its effect on the tubules. In animals its administration led to no detectable tubular damage and to no significant alteration in the blood chemistry or in the glomerular filtration of urea or of sulphonamides. When the administration of caronamide was stopped, there was a rapid return of tubular function to normal, even after caronamide had been administered for several weeks. Tubular reabsorptive mechanisms, such as those for glucose, were unaffected during its administration.

Beyer's conception of the mode of action of caronamide was that it inhibited some enzymatic component of tubular excretion and thereby blocked the particular system involved in the excretion of penicillin. The inhibition by ephedrine of tyramine deamination by amine oxidase is cited as a parallel in-vitro inhibition.

Crosson et al. (1947) studied the effects of the administration of caronamide to persons receiving penicillin by intramuscular injection and by mouth. They found that the blood-penicillin levels were raised to 2–7 times greater than during the control periods. Seeler et al. (1947) found that when caronamide was administered in doses of 2 g. four-hourly to patients over 60 years of age there was a pronounced increase in the plasma-penicillin levels. It appeared necessary to give 4 g. four-hourly to younger persons to produce the same effect; but, when this dose was given, the blood-penicillin levels produced by the injection of 100,000 units of penicillin were higher than those produced by the injection of 300,000 units without caronamide. Boger et al. (1947) confirmed the action of caronamide on penicillin excretion in man. With caronamide they maintained plasma-penicillin levels of 30–60 units per ml. They found, however, that the effect of the same dose was not always constant in the one patient at different times.

Dosage.—Enough caronamide has to be given daily to inhibit tubular function adequately. Methods devised for the estimation of plasma-caronamide are not practical for routine use, but from experimental studies it seems necessary to attain plasma-caronamide levels of 20–30 mg. per 100 ml. (Boger et al. 1947). Probably the effective dose varies somewhat from patient to patient according to the individual renal function, but in most cases 20–24 g. in twenty-four hours will produce the required blood-caronamide level and leads to significant tubular inhibition. In children it may be necessary to use the adult dose to produce the required effect.

Phenolsulphonephthalein Test.—Phenolsulphonephthalein is excreted by the same tubular mechanism as penicillin, and the administration of caronamide leads to a considerable decrease in the excretion of the dye during the first hour following its intravenous administration. It has been claimed that, if sufficient caronamide is given to inhibit tubular excretion of the dye, the excretion of penicillin is also inhibited (Boger et al. 1947).

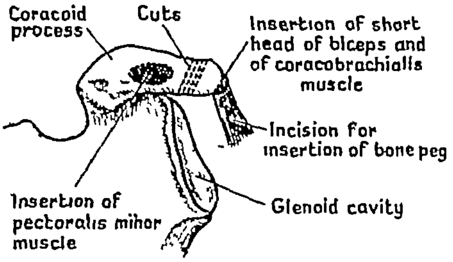
CLINICAL STUDY

Our experiment was designed to determine the effect of caronamide on the blood-penicillin levels which can be achieved by repeated three-hourly or four-hourly injections, by a single injection, and by penicillin given by mouth.

Except where otherwise indicated all the patients were men, aged 20–52, convalescent from acute infections or conditions such as sciatica, and in none of them was there any evidence of renal impairment. They all received a standard hospital diet with no restrictions regarding salt or fluid intake. Penicillin was given intramuscularly as the sodium salt dissolved in normal saline solution at a concentration of 50,000 units per ml., and by mouth as the calcium salt. All the patients were given caronamide 3 g. three-hourly, one dose being omitted during the night, so that a total of 21 g. was

It is a clinical observation that those shoulders which are rather stiff after operation are unlikely to suffer further dislocation. It seems probable that both the stiffness and the stability of the head of the humerus are due to the adhesions.

BANKART'S OPERATION



Coracoid process
Cuts
Insertion of short head of biceps and of coracobrachialis muscle
Incision for insertion of bone peg
Insertion of pectoralis mihor muscle
Glenoid cavity

The operation most used at present is the one usually attributed to Blundell Bankart (1938), which is similar in many respects to that of Oudard (1924). The joint is approached through a straight incision in the deltopectoral groove; the coracoid process and the subscapularis muscle are then divided, and an attempt is made to repair the capsule., The practical difficulties in this step are considerable, The lesion is situated deep down in a narrow wound which easily fills with blood. The difficulties in drilling the necessary holes in the glenoid cavity and in inserting the sutures are great. Even if the torn structures are reapposed, there is considerable doubt whether they will be permanently united by the formation of fibrous tissue.

In the repair of the wound the subscapularis muscle is sutured. Muscle has a good blood-supply and unites well, provided it is kept in apposition; but, being deficient in fibrous tissue, it holds sutures poorly. During the spasms which occur when the patient is coming round from the anæsthetic the muscle must contract, throwing tension on these sutures. The sutures may tear and weaken, allowing the muscle to retract and a small gap to appear between the cut ends. The muscle is thus elongated and weakened. Thus inadvertently this operation, by reducing the power of the subscapularis muscle, may restore the normal balance between this muscle and its opponents.

The next stage in the repair of the wound is the suture of the coracoid process. The coracobrachialis muscle and the short head of the biceps muscle are attached to the distal fragment. These, by their contraction, will tend to pull this fragment downwards; again it seems likely that a gap is formed between the two fragments which subsequently becomes filled with callus and bone. The coracoid process is thus elongated and may act as a buttress in front of the head of the humerus, thus fortuitously increasing the "functional" articular area.

PRESENT OPERATION

This is based on the assumption that recurrent dislocation of the head of the humerus after Bankart' operation might in part be prevented by the elongation of the coracoid process as just described. It was hoped that a coracoid process somewhat resembling that foun in patients with Erb's palsy could be created. If suc a buttress could be built up it would adequately preven further dislocation of the head of the humerus.

The coracoid process is approached through a straig incision. The deltoid and pectoral muscles are retracte The part of the coracoid process distal to the insertio of the pectoralis minor muscle is divided by four obliq cuts with an osteotome (see figure), care being taken not strip from the resulting pieces of bone the fibrous tiss carrying their blood-supply. The pieces of bone are the levered apart, the most distal fragment being displac downwards and outwards. As many chip grafts possible are forced between the pieces of coracoid proce No attempt is made to dissect the process clear, for is from the attached soft tissues that the bone deriv its blood-supply. The coracobrachialis muscle and th short head of the biceps muscle, at their insertions in the tip of the coracoid process, form a rounded musc almost surrounded by an envelope of fibrous tiss A vertical incision is made in this fibrous tissue (s figure) to enable a peg graft to be driven upwards in the tip of the coracoid process. The envelope of fibro tissue is next sutured to hold the bone peg in the muscl The wound is closed in layers. The patient's arm kept by his side in a sling for some six weeks to all the bone to consolidate.

RESULTS

The cases recorded in the accompanying table w all in Servicemen aged 20–40 years. In none of the was there any history of epileptic fits. The series inc all the cases admitted to hospital during this period.

On 15 patients 16 operations were performed (1 pati was subject to recurrent dislocation of both shoulder

* C, caronamide 3 g. three-hourly. C_4, caronamide 4 g. four-hourly.

taken in the twenty-four hours; the drug was dispensed in 0·5 g. tablets. *In all cases, except where otherwise* indicated, this dose of caronamide was given for twenty-four hours before its effect on blood-penicillin levels was determined. Phenolsulphonephthalein-excretion tests, blood-urea-nitrogen estimations, and urine examinations were carried out before and during caronamide administration.

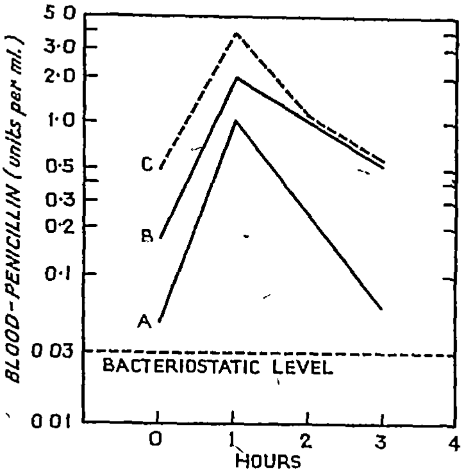

Fig. 1—Effect of caronamide on blood-penicillin levels when intramuscular penicillin 100,000 units is given three-hourly (logarithmic curves): A, before caronamide was given; B, after 24 hours' administration of caronamide; C, after 48 hours' administration of caronamide. Note increased effect on third day.

RESULTS

Repeated Intramuscular Injections of Penicillin.—The effect of caronamide in raising the blood-penicillin levels was determined in 6 cases in which repeated injections of penicillin were given three-hourly or four-hourly. The plasma-penicillin levels were estimated by the method described by Mackie and McCartney (1948). Of the 6 patients 5 had syphilis and 1 bacterial endocarditis. Fig. 1 shows a typical example. It will be noted that curve C obtained after forty-eight hours' caronamide therapy, is significantly higher than curve B, which was recorded on the second day. The detailed results in the other cases are given in the accompanying table. Fig. 2 shows the effect of caronamide administration on the four-hourly injections of 200,000 units of penicillin. The blood-penicillin levels achieved with a single injection of 500,000 units of penicillin are interpolated (curve C), and it is evident that the levels achieved with 200,000 units of penicillin with caronamide are greater than those produced by the single injection of 500,000 units without caronamide.

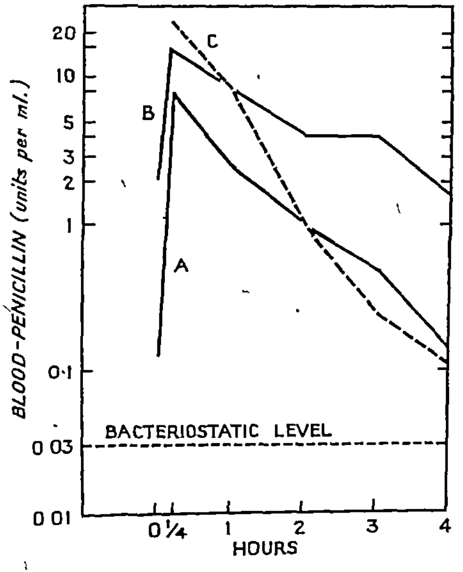

Fig. 2—Effect of caronamide on blood-penicillin levels: A, blood-penicillin levels when intramuscular penicillin G 200,000 units is given four-hourly without caronamide; B, readings from the same case after caronamide had been given for 24 hours; C, blood-penicillin levels achieved with a single intramuscular injection of 500,000 units of penicillin.

Single Intramuscular Injections of Penicillin.—In 10 cases caronamide was given to determine its eff *on the duration of blood-penicillin levels following a* sing injection of penicillin. The phenolsulphonephthalein te was carried out on the first day of the experiment, ar thereafter the blood-penicillin levels achieved by a sing injection of penicillin were recorded (see table). Fro the second day caronamide 3 g. was given three-hour until the end of the experiment. After twenty-fo hours' administration of caronamide the dye test w repeated, *and* the blood-penicillin levels following th same dose of penicillin were again determined. Wh penicillin was demonstrable in the blood for more th six hours, the administration of caronamide was co tinued, and a further *injection of penicillin* was giv *next day.* On this day the blood-penicillin levels we estimated 6–10 hours after the injection (see tabl In 3 cases repetition of the phenolsulphonephthal test twenty-four hours after the caronamide was stopp showed that tubular function had returned to norm. Fig. 3 shows a composite curve made from the avera results *obtained from* 4 patients *receiving intramuscul* penicillin 100,000 units. It will be noted that t greatest effect is on the duration of the blood-penicill levels, which are maintained for twice as long wh caronamide *is* given. In 2 cases the blood-penicil levels were not significantly raised. A similar findi has been reported by American workers (Seeler et 1947).

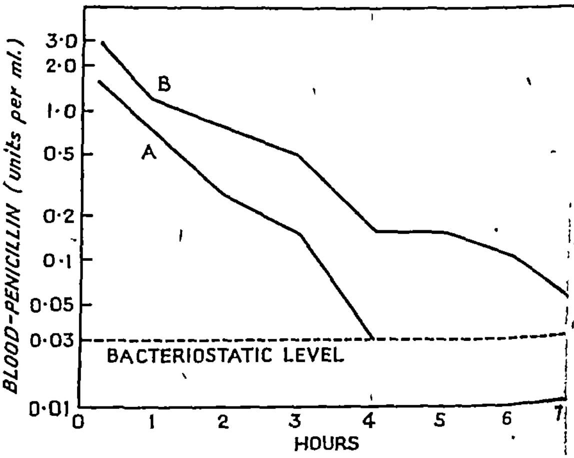

Fig. 3—Average readings from 4 patients given intramuscular penici 100,000 units: A, without caronamide; B, after caronamide had be given for 24 hours.

Penicillin by Mouth.—Recent experimental clinic studies have shown *that not more than* 35% of penicill given by mouth appears in the urine (McDermott et 1946). It has also been shown that there is comparative little destruction by gastric juice unless the pH is under (Stewart and May 1947). Penicillin is probably absorb in the upper part of the small bowel, being rapid destroyed farther down the alimentary tract *penicillinase-producing organisms.*

In our studies we did not try to neutralise the gastr acidity. All the patients had breakfast at 8 A.M., an calcium-penicillin powder, *measured by weight,* was give in a rice-paper cachet at 10 A.M. The other condition of the experiment were essentially the same as thos already described. Blood-penicillin levels following single dose of penicillin by mouth were estimated on th first day and *again after* twenty-four hours admini stration of caronamide. Phenolsulphonephthalein test were also carried *out* as described in the other exper ments. The results are shown in the table. Fig. gives a composite curve of the results obtained from 4 patients *given calcium penicillin* 50,000 units by mouth. When penicillin was given without caronamide after their discharge from the hospital nursery were then admitted to the children's hospital.

Clinical Features.—These were usually refusal of food, ing (often intractable), and diarrhœa, sometimes yellow stools. Later came collapse, signs of dehydra- increasing weakness, drowsiness, rapid loss of weight, occasionally pyrexia, seldom rising higher than F.

Course.—Usually the babies either died of toxæmia two or three days at the latest or recovered after sive treatment. In fatal cases there were increasing ess, collapse, and failure of the circulation, often n by severe meteorism. During the illness the ght of the babies often fell to 30% or even 40% w their birth-weight.

Age.—The age of the babies admitted to this clinic 3–27 days, but most of the babies were aged 6–18 s when the first symptoms were observed. Newborn nts alone were affected, as other writers have pointed . There was no difference in incidence among breast- partially breast-fed, or bottle-fed babies.

Treatment in this clinic consisted in combating toxæmia: vation, followed by special diet and supplemented blood-transfusions. During the period of starvation ot broth was given in preference to weak tea, because believe carrot broth purges the intestine and absorbs ns, besides providing a small amount of nourishment. period of starvation lasted usually two or three days, times longer, until a stage of detoxication was hed. Then we started giving buttermilk with 2% flour, at first without and then with 5% of a special r. Eventually a small quantity of breast-milk, ly skimmed, was given. As an adjuvant, especially the period of starvation, we gave infusions of blood, preferably plasma, eventually changing to 'Periston.' saline plus the glucose either as a supplement ternatively (20–40 ml. according to weight, some- twice a day). The average treatment in this hospital about three weeks; elsewhere it had apparently continued longer.

gnosis generally depends on the virulence of the organism. This virulence may vary so much in ent epidemics that, in assessing the value of any ment, one must compare the results in epidemics ual severity. A factor, which we had no opportunity termining exactly, but which is also pointed out Field et al. (1943), is that during the epidemic the -mortality rises, until it may reach 100%; this is se the virulence of the organism is increased by age. The case-mortality in different epidemics s from 12 to 80%, and it is usually not less than when large numbers of infants are involved (Rice al. 1937, Cooper 1937, Smellie 1939). In the three emics observed by me the rate was 22%: and, if results from two other children's hospitals in wick are included, it was 40%.

Ætiology.—Published opinions on the ætiology of the se are not unanimous. Thus, Rice et al. (1937), enberg and Wronker (1938), Forbes and Olsen (1939), ddy et al. (1939), Cron et al. (1940), Lembcke (1941), d I found that all bacteriological examinations, the ch for a virus, the examination of food and stools, d the necropsy findings were completely without result. epidemic Hotz (1932) ascribed to a *Staph. aureus* oduced by a nurse with an incompletely healed uncle. Felsen (1939) accuses the Flexner bacillus: an et al. (1940) the hæmolytic streptococcus; (1937), Frick (1941), and Lyon and Folsom 1941), Pfeiffer's bacillus; Goebell (1943) *Proteus vulgaris* d *Ps. pyocyanea*; Cass (1941) *Bact. aerogenes*. In one epidemic observed by me *S. enteritidis* Gaertner was covered; but in the other two epidemics we could not isolate any likely organism.

The high infectivity, the epidemicity, and the rapid spread of the disease suggest a virus of high pathogenicity perhaps closely allied to the influenza viruses. The organisms described by other writers should in my opinion be regarded as secondary invaders, or as symbionts with the true organism not yet discovered.

Young pigs are attacked by a sort of influenza starting with cough and bronchitis, soon leading to severe diarrhœa, and generally progressing so quickly and lethally that often 100% die. Farmers know that the infection is transmitted by droplets and that once sties are infected they are dangerous to new litters for long afterwards. They therefore use such sties for other animals before putting in young pigs again. This disease seems to resemble the gastro-enteritis of infants in some respects. Professor Wagener, of the Hygiene Institute, Veterinary High School, Hanover, informed me that the cause might in the first place be the conditions in the communal sties. Later Waldmann and Köbe (Riems) isolated a pneumotropic virus of the influenza group. Other bacilli found, such as *Bacillus bipolaris* and pasteurellas, would be regarded as only incidental. By improving conditions, and especially by avoiding communal sties, it is possible to get rid of the disease completely. Furthermore H. Hormann, in a paper on the ætiology of necrotic jejunitis shortly to be issued by the Bernhard Nocht Institute, refers to results obtained by Köbe in infectious gastro-enteritis in pigs, among which there have been severe epidemics, especially in young pigs. Thus there is in both cases an analogous condition in the rearing of animal sucklings.

The Japanese disease called "ekiri," seems to be a similar condition. This is an epidemic diarrhœa, especially attacking infants, and resulting in a case-mortality up to 80%. The clinical features include a very acute onset, high fever, collapse, cyanosis, and paralysis of limbs, followed by convulsions and unconsciousness, and eventually death. The causative organisms are believed to be of the *Bact. coli* or pseudo-dysentery groups. Adult contacts of babies suffering from ekiri often fall ill with a sort of dysentery.

PREVENTION

Combating an epidemic after it has broken out appears to be hopeless, and the unanimous opinion is that the infected hospital should be completely closed for a time. Prevention is therefore extremely important.

Field et al. (1943) recommended the accommodation of as few patients as possible in each ward: wider spacing of beds; face masks and surgical gowns for nurses; and immediate isolation of new cases of gastro-enteritis. In their view all children under 2 years of age admitted to hospital with dyspepsia should be nursed in isolation cubicles; if an epidemic of severe diarrhœa should break out, new admissions of infants should be stopped temporarily, as many infants as possible sent home, and the remainder widely distributed among older children and adults; and that homes for infants ought to be considered only as emergency war institutions. What a difference from the older view that neonatal wards should always be large!

Rice et al. (1937) emphasised the importance of aseptic nursing of all infants, including the sterilisation of all linen and food and a thorough disinfection of hands. Some writers have recommended that different nurses should be employed for feeding and for cleaning the babies, to prevent the transfer of organisms from the baby's anus to its mouth. Felsen (1939) even recommended the employment of a special epidemiologist. All these suggestions show that the prevention and combating of an epidemic are a grave problem, and that the pathogenicity of the germ must be extraordinarily high. In view of these circumstances, all authors emphasise the fact that temporary closure of the infected

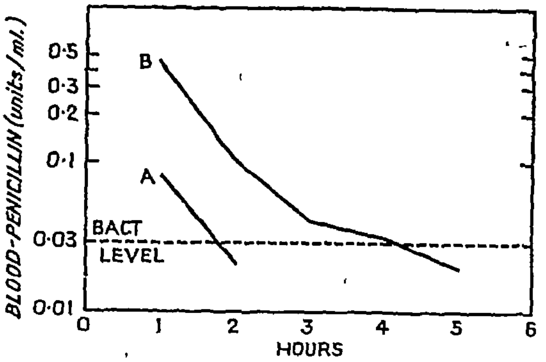

Fig. 4—Average readings from 4 patients given calcium penicillin 50,000 units by mouth: A, without caronamide; B after caronamide had been given for 24 hours.

it was not present in the blood in detectable amounts for as long as two hours, but after caronamide had been given the blood-penicillin level was five times as high, and the effect lasted for four hours.

These results are so striking that it seems possible to us that caronamide may interfere with the destruction of penicillin in the alimentary tract besides delaying its excretion by the kidney. To clarify this point the urinary excretion of penicillin is being determined. The results will be published later.

Inhibition of Tubular Function.—Of 19 of the patients in this study, when the phenolsulphonephthalein test was carried out, 15 had a reduction of excretion in the first hour to less than 70% of the control reading. In only 1 of the 4 remaining patients were the blood-penicillin levels significantly altered. These preliminary observations suggest that the phenolsulphonephthalein test is a simple clinical guide to whether the excretion of penicillin by the renal tubules is being adequately inhibited.

Toxicity.—Of 24 patients who received an average dose of 60 g. of caronamide in two and a half days, none had renal damage as shown by a raised blood-urea-nitrogen level or by the appearance of albumin or of cellular elements in the urine.

Caronamide was invariably present in the urine in solution and could be precipitated by the addition of dilute acetic acid. The precipitate first appeared when the pH of the urine reached 5, and was maximal at pH 4. Because of the considerable acidity required for precipitation it is probably unnecessary to alkalinise the urine, but an adequate output of urine should be ensured.

In 22 of the 24 cases a substance was detected in the urine which reduced Fehling's and Benedict's solutions. Its exact chemical composition is at present unknown. Though it gives a positive Bial's orcinol test, reactions for glycuronic acid have been consistently negative (Rapoport et al. 1948); and, though it is likely to be a pentose, attempts to isolate the osazone have so far been unsuccessful. This substance appeared in the urine when caronamide was being given alone as well as during the administration of penicillin.

Of the 24 patients 2 complained of headache and 1 other of slight nausea. No drug rashes or drug fever were noted (cf. Boger et al. 1947).

DISCUSSION

Our findings are in agreement with the recent American work. They show that caronamide can be given by mouth in doses sufficient to delay the excretion of penicillin and to raise the blood-penicillin levels. Systemic toxicity is apparently low. There is no evidence of damage to the kidney, and the tubular inhibition is readily reversed by stopping the administration of caronamide.

It may be taken as axiomatic that all potent dr are two-edged weapons capable of producing toxic effec Unfortunately in the case of many preparations seve years may elapse before these are clearly recogni For this reason a drug which interferes with tubu function, no matter how harmless it may appear, sho be used with caution. This is especially the case w caronamide because of the appearance in the ur of a reducing substance which is apparently a pent and may well be a product of disorganised cellu metabolism.

For these reasons we suggest that, until caronam has had a more extensive clinical trial, its use sho be restricted to those cases in which the maintenance high blood-penicillin levels is essential.

This study was suggested by Prof. D. M. Dunlop, to wh we are indebted for advice and criticism. We are grat to Dr. Beyer, of Messrs. Sharpe and Dohme Ltd., Philadelp for the supplies of caronamide, and to Dr. H. M. Walker, Glaxo Laboratories Ltd., for the supplies of penicillin.

MASS DEATHS OF INFANTS

RÔLE OF CROSS-INFECTION

THILO BREHME
Dr. Med.
CHIEF PHYSICIAN, CHILDREN'S HOSPITAL, BRUNSWI

THE possibility of cross-infection is a strong argum against nursing infants in hospitals. For this rea some authorities insist that babies should be nursed home, and utterly condemn their admission to insti tions. Not only does mass nursing help to spread cr infection, but also it is possible that the pathogenic and virulence of organisms in a hospital may be lug than they are outside, the continual change of patie leading to increased virulence by passage.

The incidence of cross-infection is most clearly sho by the mortality of children in hospitals. For instan Van Ingen (1915) reported that of 28,210 infants un 2 years of age in foundling hospitals in the State New York in 1910–15, 42·25% died, though the gene mortality of infants in that State in the same age-gro was only 8·7%.

EPIDEMIC DIARRHŒA

Since 1924, and to an increased extent since 19 epidemics of diarrhœa with a high mortality have be reported from neonatal wards and nursing-hom I experienced similar epidemics in 1939, 1940, and 19 in a big lying-in section of a hospital. The characterist of all these outbreaks were much alike.

Onset.—In the neonatal wards or nurseries, isolat cases of digestive trouble suddenly arose, the ch initial symptoms being refusal of food and changes the stools. The disease then spread explosively like epidemic. Some of the babies from the neonatal war when infections, especially those of the skin, arise in the nursery bathing of babies must be stopped altogether, as the bath cannot possibly be properly disinfected. The need for the greatest cleanliness was repeatedly urged on the nurses, but perhaps not always properly observed by these inexperienced attendants, especially at night. Feeding difficulties were treated by careful feeding; drugs such as 'Tannalbin,' 'Rivanol,' and sulphonamides were used where indicated; food was given by tube to avoid vomiting; and infusions of saline and glucose were given. Severe cases from the homes at Wolfsburg and Rühen were sent to hospital. Attempts were made to identify the causal organism by bacteriological examinations of water, milk, and stools —but without success.

All this shows that in all four homes the true cause of the catastrophic consequences of nursing patients in these homes was not recognised; the risk of cross-infection was not properly appreciated. Thus doctors came to look on the mass deaths as inevitable and due to factors beyond medical control. The physicians of the four homes attributed the mass deaths to lack of mother's milk, insufficient adaptation of the infants to artificial feeding (Eastern European babies having for many generations been breast-fed), and innate lack of vitality, the result of the mother's working too long before her confinement, of her being insufficiently fed, and even of psychological influences (unwanted child, depression by separation from her country), and of attempts at abortion.

DISCUSSION

Mother's milk undoubtedly provides some protection against pyogenic infections, but in epidemics of gastro-enteritis the babies fall sick whether they are fed on the breast or artificially. The assumption that a newborn baby is less well adapted to artificial feeding because its parents and ancestors have been breast-fed contradicts [illegible] only the law of non-inheritance of acquired factors [illegible] all experience.

[illegible] some extent the unborn child may be injured by the mother living in bad conditions during her confine-[illegible], perhaps also by psychological influences, but certainly not by attempts at abortion. The birth-weight of babies is lower in war-time than in peace-time, and the baby's reserves of vitamins are certainly lower than normal, but on the whole the child grows in the mother's body like a parasite—i.e., it takes what is necessary for [illegible]ding its body if it is available.

The influence of mass nursing has been thoroughly [illegible]construed in these cases. The view of the physician in one of the homes is typical:

> "Taking the babies born with a lack of vitality and incapable of sufficiently adapting themselves to artificial feeding, had they been left to the individual care of their mothers, without being breast-fed by them, just as many of them would have died (though relatively fewer in special homes), simply because they were weak by birth and not accustomed to artificial feeding."

This is wrong; the truth is just the opposite. Reared in a family by their mothers (or other persons) they would have been endangered neither by cross-infection nor by gastro-enteritis of the newborn, even though they were artificially fed or their birth-weight was below normal owing to war conditions. It is tragic that such mistakes should have led to non-recognition of the true causes of the catastrophe and thus have contributed to the deaths of a large number of children.

SUMMARY

Cross-infection, previously believed to have been overcome, is still adversely affecting the results of nursing infants in homes.

It is chiefly responsible for the epidemics of infantile diarrhœa, which in many places have led to mass deaths in neonatal wards and infants' homes.

The information published up to now on this condition is tabulated, and the clinical features, course, treatment, prognosis, ætiology, and prevention are discussed.

The unfavourable influence of war on cross-infection is explained, with special reference to infants' homes for displaced persons in Germany.

The following suggestions are put forward:

(1) Homes and other large institutions for infants are permissible only in times of emergency, and even then they must meet all requirements with regard to equipment and nursing and medical staff.

(2) The healthy child should be born and reared in the family to avoid the danger of epidemic gastro-enteritis.

PARA-AMINOBENZOIC ACID IN LEUKÆMIA

EFFECT ON THE LEUCOCYTE-COUNT

H. B. May
M.A., M.D. Camb., M.R.C.P.
DIRECTOR OF CLINICAL LABORATORIES

J. Vallance-Owen
M.A., M.B. Camb., M.R.C.P.
RESIDENT PATHOLOGIST

THE LONDON HOSPITAL

Though leukæmia has been accepted as a neoplastic disease by Willis (1948) from considerations of morbid anatomy, and by Furth (1946) from experimental evidence, and though this view is supported by most hæmatologists, nevertheless the tissue-culture experiments of Israëls (1940) still hold out the faint hope that maturation of the leukæmic cell can proceed to the normal leucocyte under suitable nutritional conditions. To pursue this possibility we have used *p*-aminobenzoic acid, a well-established essential metabolite for many bacteria, in the treatment of leukæmia.

Five cases of chronic myeloid leukæmia, one of chronic lymphatic leukæmia, and one of acute leukæmia were treated.

Dosage.—The dose of *p*-aminobenzoic acid was related to that used in the treatment of rickettsial infections. All the patients received 0·5 g. per lb. of body-weight per 24 hours, divided into 2-hourly doses from 6 A.M. to 10 P.M. Blood concentrations were estimated daily by a modification of Bratton and Marshall's method for sulphonamides. Values between 60 and 100 mg. per 100 ml. of blood were obtained after the first 24–48 hours.

RESULTS

All five patients with chronic myeloid leukæmia showed a remarkable drop in the total leucocyte-count, irrespective of whether radiotherapy had been previously given or not. Within 21 days the total leucocyte-count could be brought in all cases to within normal limits, institution is the only possible way of extinguishing an epidemic. With this my experience makes me agree.

EFFECT OF WAR

Such epidemics having already been observed in peace-time it is only natural that war should aggravate them. Steinert (1921) stated that from 1913 to 1916 in the foundling hospital in Prague mortality rose from 4·7 to 15·8%. The reasons why a war increases cross-infection are chiefly to be found in the following facts:

(1) The longer a war lasts, the more primitive conditions generally become, especially so far as they relate to children (cleanliness, lack of linen and soap, shortage of nurses, industrial employment of the mother, &c.).

(2) Modern war, particularly aerial war, and the employment of foreign labourers with their families, especially the employment of foreign women, lead to overcrowding of infants because of the establishment of numerous homes or hostels where babies and young infants, generally separated from their mothers, are inevitably exposed to the dangers of mass nursing, an accumulation of infections, and gastro-enteritis. People had forgotten how easily infants fell ill; and with the necessity for evacuating children as a protection against raids the consequences of such measures were at first lost sight of.

(3) With the mass movements of armies, evacuees, or displaced persons there was an increased exchange of bacteria among the population, leading to an increase in virulence by passage.

During the late war reports of German epidemics were not published, and, with few exceptions, foreign literature was unobtainable in Germany. In England Field and her colleagues (1943) reported a case-mortality of 80% among infants with gastro-enteritis at an emergency children's home. In June, 1946, Dr. Goebell wrote (private communication), that in Düsseldorf "many epidemics of gastro-enteritis are again raging in hospital nurseries, some with an enormous mortality." From a camp in Oksboel, Denmark, where many German refugees from East Prussia were accommodated I had news by letter that "all children under 2 years of age died of diarrhœa." The *Daily Mail* of May 29, 1946, reported that, in five ships carrying wives and babies of American soldiers from England to the U.S.A., a "mysterious illness" broke out, which appears to have been severe epidemic diarrhœa. The babies had assembled in a camp, where they awaited sea transport. Presumably conditions in that camp were not ideal, or the massing led to cross-infection. To prevent further damage the right decision was taken—to stop the transport of babies until they were older. Dr. A. Peiper reports (private communication) that he saw a severe epidemic of dyspepsia in newborn infants with at least 10 deaths in a short period during 1942–43 at Wuppertal. These were mainly breast-fed babies. The *Times* (Dec. 16, 1946) and the *Sunday Express* (Dec. 22, 1946) reported minor epidemics among babies, with a total of 30 deaths, which had occurred in Leicester (15 deaths) and other English cities. The morbidity was apparently somewhat higher, but figures were not quoted.

WAR NURSERIES IN GERMANY

Far more serious examples of cross-infection were noted in camps established for babies of displaced persons from the East by numerous armament factories all over Germany. The central authority (with an eye only to the labour pool) ordered that "in a simple but hygienic manner" homes were to be established for newborn and other babies of displaced persons from the East; that babies were generally to be looked after by women of the same nationality; and that the mothers should go to the hospital nursery not earlier than a few days before their confinement, and should resume work, at the latest three weeks post *partum*, when the newborn babies were to be brought into babies' homes. These orde presumably drawn up without consulting a doctor, a certainly without the advice of a child specialist, (not take into account the consequences of overcrowdi of infants separated from their mothers and looked af by insufficiently trained women. These orders led cross-infection on a large scale, like a mass experime though it was not recognised as such by inexperienc doctors and still less by the laity.

EPIDEMIC DIARRHŒA IN INFANTS IN INSTITUTIONS

Authority	Year(s)	Place	No. of cases	Case-mortali (%)
Cohen et al. (1933)	1933	Brooklyn Hospital, New York	175	35
Rice et al. (1937)	1934–37	19 hospital nurseries in New York	505	46
Cooper (1937)	1937	Royal Children's Hospital, Glasgow	300	47
Greenberg and Wronker (1938)	1937	New York Babies' Home	52	23
Smellie (1939)	1939	Children's Hospital, Birmingham	500	10
Campbell and Cunningham (1941)	1937–39	Park Hospital, London	574	29
Brehme (1943)	1939–41	Ward for newborn, Landeskrankenhaus, Brunswick	53	12
Goebell (1943)	1939 1940	Various hospital nurseries, Düsseldorf	148 231	23 15
Brehme (unpublished)	1939–41	3 epidemics in Brunswick	120	40

After the end of the war I studied the conditi in four of these homes for babies of displaced pers from the East. The infants had been accommodat in huts, some of which were furnished quite adequatel but, though kept fairly clean, were often infested w bugs. There was a sufficient supply of medicine a appropriate food, but linen was rather scarce. Th nurses were female displaced persons from the Eas trained by German nurses. The doctors were very bus with other practice and were assisted by foreign docto medical students, or midwives. The children's home Broitzemerstrasse, Brunswick, was staffed by forei doctors only.

So far as the records could be obtained, the infan either developed furuncles and then died of sepsis, more usually, contracted a typical epidemic gastr enteritis. The mortality in these homes was extr ordinarily high in comparison with the figures usual accepted for nursing-homes before the start of this ne phase of cross-infection, characterised by epidemics gastro-enteritis of the newborn. Nevertheless, it is with the limits of the American, British, and German figur shown in the accompanying table. The mortality four German homes for displaced persons studied b me was as follows:

Home	*No. of infants in home*	*No. of deaths*
Velpke	102	89 (87%
Wolfsburg	About 80	About 45 (56%
Rühen	" 490	" 285 (58%
Brunswick (May, 1943, to June, 1944)	351	" 174 (50%

The doctors and nurses in the homes repeatedly trie to get better results. Furunculosis was treated in th usual manner with lotions, ointments, dressings, an surgery. Bathing ill and healthy babies in the same bath sometimes in the same water, unfortunately encouraged the spread of the boils and perhaps also of diarrhœa. Steinert (1921) expressly points out in his report that and depressed at high concentrations of *p*-aminobenzoic acid.

We wish to thank Messrs. Ward Blenkinsop and Co. for supplies of *p*-aminobenzoic acid, and Dr. R. R. Bomford, Dr. A. E. Clark-Kennedy, Dr. F. Ellis, Dr. Horace Evans, and Prof. C. Wilson for access to patients under their care.

DESPECIATED BOVINE SERUM

DAVID ANNIS
M.B. Lpool, F.R.C.S.
RESEARCH FELLOW IN SURGERY, DEPARTMENT OF SURGERY, UNIVERSITY OF LIVERPOOL

EDWARDS (1944), working in the Department of Surgery in the University of Liverpool, described a method of preparing despeciated bovine serum as a substitute for human plasma. Later he recorded its use in 200 cases (Edwards 1946). Since then Massons (1946) in Barcelona has reported favourably on the use of a very similar formol-ammonia-heat-prepared serum in 200 cases and in 1000 experimental injections. Elka et al. (1947) confirmed his experience, but Bing (1948) and Boesen et al. (1948) found that in serum prepared by the method of Massons the osmotic tension was reduced by 50% and that it was still capable of toxic and antigenic effects.

In Edwards's original method the serum was separated, diluted with water in the proportion of 4 parts of serum to 1 part of water, bacterially filtered, despeciated, and collected in sterile bottles. Despeciation was effected by adding formol and sufficient ammonia to convert the excess formol to harmless hexamine. This prevented coagulation during the next stage, when the serum was heated to 72°C for 30 min. Edwards considered that the despeciating factor was heating to 72°C and not the addition of formol and ammonia. He showed that the addition of these substances to bovine serum without heating did not lead to despeciation. Jacobs and Sommers (1939) had shown this to be true for many mammalian sera.

This work was carried further in this department to discover the chemistry of this change and the exact nature of the end-product. It soon became evident that the chemistry of formol proteins was very complex and ill understood, and that it would be difficult to prove that serum prepared by this method was protein of high molecular weight acting in every way like the human plasma proteins and therefore a satisfactory substitute for human plasma.

Because of these difficulties a simpler method of preparation without using formol was sought. Accepting Edwards's belief that heating to 72°C was the all-important despeciating factor, we looked for other methods of preventing coagulation on heating, and found it possible to avoid coagulation by adding, before heating the serum, sufficient sodium hydroxide to bring the pH to 9. The serum showed an exactly similar physical change to that described by Edwards, assuming a greenish opalescence and a slight fluorescence. In heating the serum we fulfilled the exact instructions laid down by Edwards, bringing the serum to 72°C by raising the water-bath temperature from 60 to 75°C as rapidly as possible and maintaining it for 30 min. The product was cooled and the pH returned to pH 7 by the addition of hydrochloric acid.

This at first sight appears to be a more simple method, gaining the same ends and avoiding the use of formol. Serum treated in this way lost its power of agglutination and hæmolysis when added to human blood.

Experiment I.—Serum was added in equal quantities to four batteries of 40 test-tubes each containing a sample of human blood of a different group or subgroup. At 2 hours and at 24 hours, both at room temperature and at body temperature, the tubes were examined. In no tube was there hæmolysis or agglutination. A similar control series with untreated serum led to agglutination and hæmolysis in every tube.

We were satisfied that the agglutinins and hæmolysins had been destroyed by this process.

To discover the composition of the product we submitted samples of the serum for electrophoretic and ultracentrifuge examinations at the Lister Institute for Preventive Medicine. The report showed that our product was far from satisfactory:

Report.—"It was obvious from the ultracentrifuge runs and by analysis of the plates that 90% of the protein was aggregated in the samples B and C, and this aggregated material sedimented to the bottom of the cell very rapidly when the rotor speed reached 20,000 r.p.m. The residual protein appeared to sediment, like normal albumin, at 60,000 r.p.m.

In the electrophoresis apparatus the normal plasma showed albumin and α, β, and γ globulin; but no fibrinogen was detectable. Both the despeciated samples appeared to consist electrophoretically of a single abnormal component essentially with a trace of albumin."

Protein osmotic tension was estimated at the Lister Institute by the method of Adair and Adair (1925). The sera were dialysed against $M/15$ phosphate buffer ($M/30$ KH_2PO_4 + $M/30$ $Na_2H\ PO_4$) of pH 6·8. The same buffer mixture was used as outer fluid in the osmometers, which were equilibrated for 14 days at 0°C. The osmotic pressures of the sera were measured in mm. of protein solution and calculated as mm. Hg after measurement of the densities by pyknomity at 0°C. This showed a protein osmotic tension of only a fifth of that of the original serum from which it was prepared:

	Osmotic tension (mm. Hg at 0°C)	*Density*
Normal plasma	10·63	1·0201
Despeciated plasma	1·97	1·0210

BIOLOGICAL EXPERIMENTS

The object of these experiments was to observe, by repeated injections, whether this prepared serum was truly despeciated—i.e., whether it had been rendered incapable of producing anaphylaxis. For this purpose we used three groups of guineapigs.

Group 1 we used as a control so that we might be well acquainted with the features of anaphylaxis in guineapigs. We injected two guineapigs intraperitoneally with 2 ml. of raw bovine serum as a sensitising dose, followed a month later by 5 ml. Both guineapigs manifested anaphylaxis within 5 min.; one recovered in 4 hours, and the other died a typical anaphylactic death.

Guineapigs are particularly suitable for this work, since they readily manifest easily recognisable anaphylactic phenomena when injected after being sensitised with foreign protein. In a sensitised guineapig, within 2–3 minutes of the intraperitoneal injection of foreign protein, in a full attack, the animal becomes stationary its fur becoming ruffled and erect, especially over the dorsal spine. The guineapig often emits sneeze-like sounds, and there is much nose-rubbing with the front paws. Often the guineapig becomes apparently ataxic and lies with both back legs outstretched, or it may fall to one or other side. Respiratory difficulty follows, with increasing difficulty in expiration.

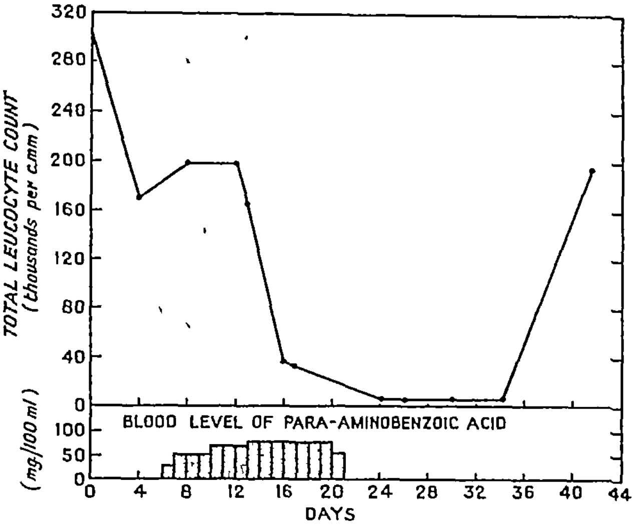

Fig. 1—Leucocyte-count in relation to blood concentration of *p*-aminobenzoic acid in chronic myeloid leukæmia.

but on cessation of treatment the count rose rapidly to its former value. Typical results are illustrated in figs. 1 and 2, and blood films before and during treatment in a typical case are shown in figs. 3 and 4.

After the count had returned to its former value a second course of treatment again produced a similar rapid fall. The differential count of the leucocytes in the peripheral blood and in the sternal marrow remained unchanged.

A case of lymphatic leukæmia with an initial leucocyte-count of 100,000 cells per c.mm. was treated for 15 days; and, although the percentage of polymorphonuclears in the blood decreased, the total leucocyte-count was unchanged.

A case of acute myeloblastic leukæmia was treated with full dosage, but the total leucocyte-count rose during treatment.

Other Effects.—In two cases the hæmoglobin content of the blood fell, in one case it remained constant, and in two cases it rose slightly, but the rise was negligible compared with that obtained when the patients were subsequently treated with radiotherapy.

Counts in all seven cases showed no change in the number of platelets.

In all five cases of myeloid leukæmia the spleen became appreciably smaller.

Toxic Symptoms.—To prevent acidosis the *p*-aminobenzoic acid was given as its sodium salt, produced by neutralisation with sodium bicarbonate. During treatment the plasma-bicarbonate was estimated daily. A drop of up to 20 c.cm. of CO_2 per 100 ml. of blood occurred in all cases, but no serious symptoms of acidosis appeared. All seven patients complained of slight nausea, but only one vomited. The most seriou toxic effect was unexplained hæmorrhage, which di not appear to be due to a deficiency of prothrombin vitamin C, or platelets. A tourniquet test did not reve any increased capillary fragility. The tendency to hæmor rhage remained unexplained, but it was probably due t a local infiltration of the walls of small vessels wit leukæmic cells, the vessels being also slightly damage by the *p*-aminobenzoic acid. Two patients died, but a necropsy only the post-mortem appearances of deat from chronic myeloid leukæmia were found.

DISCUSSION

Bichel (1948) treated six cases of chronic myeloid lymphatic leukæmia with *p*-aminobenzoic acid and th leucocyte-count rose abruptly in all of them. Zarafonet et al. (1948) treated five cases of chronic myeloi leukæmia and in each case obtained a profound dro in total leucocyte-count. Our results confirm the latt work. The discrepancy between Bichel's results and ou lies in the amount of the *p* aminobenzoic acid given.

As in the growth of certain bacteria, *p*-aminobenzoic acid can act as a stimulus to cell division at low concentrations and as a depressant in high concentrations (Sevag 1946), an action similar to that of hydrocyanic acid and other poisonous substances. Our results were due to its effect not as an essential metabolite but as a toxic substance with a far higher toxicity for granular cells of the myeloid series than for cells of the lymphoid serie for very primitive hæmic cells.

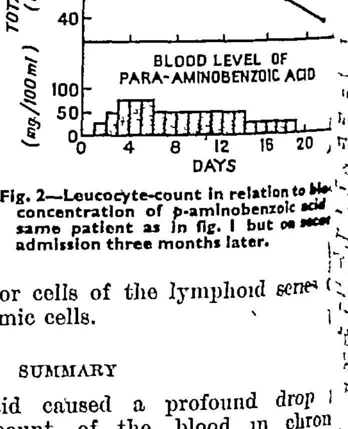

Fig. 2—Leucocyte-count in relation to blo concentration of *p*-aminobenzoic acid same patient as in fig. 1 but on seco admission three months later.

SUMMARY

p-Aminobenzoic acid caused a profound drop i the total leucocyte-count of the blood in chron myeloid leukæmia when administered in doses of 50 a day.

The hæmoglobin content of the blood was also reduc but not so much as the leucocyte-count.

The patients' general condition was little affected, b toxic symptoms were occasionally severe.

The division of myeloid cells, like bacterial multipl cation, appears to be stimulated at low concentratio

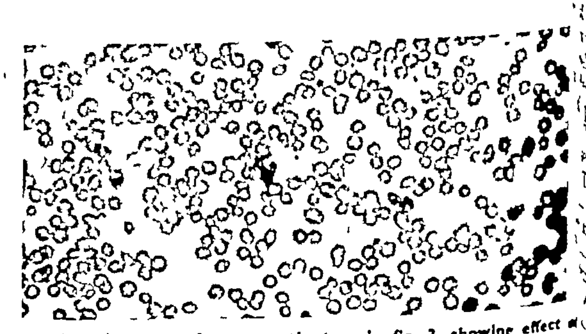

Fig. 4—Blood smear of same patient as in fig. 3, showing effect of *p*-aminobenzoic acid.

p-AMINOSALICYLIC ACID

DETERMINATION IN BLOOD AND CEREBROSPINAL FLUID

W. KLYNE
M.A., B.Sc. Oxfd, Ph.D. Edin.
LECTURER IN CHEMICAL PATHOLOGY

J. P. NEWHOUSE
B.Sc. Lond.
RESEARCH ASSISTANT

POSTGRADUATE MEDICAL SCHOOL OF LONDON

LEHMANN[1] mentions the use of Ehrlich's *p*-dimethylaminobenzaldehyde reagent for the determination of *p*-aminosalicylic acid in blood, but gives no details. We have developed the following method using Ehrlich's reagent, which is based on Morris's[2] method for sulphanilamide. The method has given satisfactory results in clinical trials in this hospital.

METHOD

Reagents

1. *p*-Toluenesulphonic acid, 20 g./100 ml. 0·2N HCl.
2. Disodium hydrogen citrate solution, 0·75*M* (39·4 g. of citric acid, dissolved in 188 ml. 2N NaOH solution, and diluted to 250 ml.).
3. *p*-Dimethylaminobenzaldehyde, 2 g. A.R. in 95% ethanol (100 ml.).
4. Sodium *p*-aminosalicylate standard. The anhydrous salt (11·4 mg.) or the dihydrate (13·8 mg.) is dissolved in 100 ml. water to give the equivalent of 10 mg. *p*-aminosalicylic acid/100 ml.

Procedure

Oxalated whole blood, 0·5 ml., or cerebrospinal fluid (C.S.F.), 1 ml., is measured into a test-tube, made up to 7 ml. with distilled water, shaken well, and stood 3 min. to lake. Next 3 ml. of 20% *p*-toluenesulphonic acid is added slowly with shaking, and the mixture is allowed to stand a further 5 min. and then filtered (Whatman no. 40 or 42 paper).

To 5 ml. of filtrate (which must be clear) are added 1 ml. of citrate buffer solution and 2 ml. of 2% *p*-dimethylaminobenzaldehyde reagent. The orange colour develops at once and is stable for some hours.

The colour is measured with a photo-electric photometer using a blue filter (e.g., Ilford no. 602). A reagent blank is used consisting of 1·5 ml. of *p*-toluenesulphonic acid, 1 ml. of citrate buffer, and 2 ml. of Ehrlich's reagent made up to 8 ml. with water.

Standards

Three standards are used, containing sodium *p*-aminosalicylate equivalent to 20, 10, and 4 mg. of *p*-aminosalicylic acid/100 ml. From the 10 mg./100 ml. standard 1, 0·5, and 0·2 ml. portions are each made up to 7 ml. with water, and 3 ml. of *p*-toluenesulphonic acid is added to each. Then 5 ml. portions of these mixtures are treated with 1 ml. of citrate buffer and 2 ml. of *p*-dimethylaminobenzaldehyde reagent. A calibration curve is constructed from the three standards, and the *p*-aminosalicylic acid content of the unknown is deduced from it.

RESULTS

Experiments in which *p*-aminosalicylic acid has been added to various body fluids in quantities equivalent to 20, 10, and 4 mg./100 ml. have given the following recoveries: plasma (oxalated) *cir.* 100%, whole blood (oxalated) *cir.* 80–90%, C.S.F. *cir.* 100%.

In two series of experiments added streptomycin (50 µg./ml. plasma) did not interfere with the determination of *p*-aminosalicylic acid.

Since the colour reaction is a general one for primary aromatic amines, it cannot be used for the determination of *p*-aminosalicylic acid if other primary aromatic amino-compounds (e.g., sulphanilamide derivatives) are likely to be present.

Reviews of Books

Fungus Diseases of the Lungs

DAVID T. SMITH, M.D., professor of bacteriology and associate professor of medicine, Duke University, North Carolina. Springfield, Ill.: C. C. Thomas. Oxford: Blackwell Scientific Publications. 1947. Pp. 59. 10*s*. 6*d*.

THE rapid advance of medical mycology has created a demand for monographs on the mycoses of individual anatomical systems. It is fitting that the first should be one on the fungus diseases of the lungs, which are probably the easiest, and certainly the most important, portal of entry for pathogenic fungi. Professor Smith's little book (no. 2 of the American Lecture Series) describes, adequately but briefly, the symptoms, clinical and mycological diagnosis, and treatment. A conflicting statement needs correction: the remark that "the lungs are rarely, if ever, the site of primary infection" in histoplasmosis is followed two pages later by a reference to "tens of thousands of primary pulmonary infections" in this disease. Such slips do not, however, detract from the value of a useful guide to a group of pulmonary disorders all too often misunderstood. It is to be hoped that Dr. Smith will expand this work into a much-needed book of reference.

Symposium on the Use of Isotopes in Biology and Medicine

Madison: University of Wisconsin Press. 1948. Pp. 445. $5.

THIS book is the report of the symposium held at Madison, Wisconsin, in September, 1947. It was produced as quickly as possible, by a photolithographic process, and the various authors had no opportunity for proof-reading; but there are few errors, and a comprehensive list of errata is provided. The subjects discussed are all of topical interest and the articles are in the form of short reviews arranged in good logical order. The historical background for isotopes in biochemistry is given by Hans T. Clarke. Urey and Seaborg write of the separation of stable isotopes and the preparation of radioactive isotopes respectively. Nier discusses the mass spectrometer, and Coryell and Kamen the detection and measurement of radioactivity in radioactive isotopes; and there is a series of articles on the use of tracers in research on the metabolism of proteins, carbohydrates, lipids, and minerals. The medical applications of radioactive tracers, both for physiological and therapeutic use are considered at some length. Moreover, the measures to be taken to protect the health and property of the users of radio-isotopes are not forgotten. This report should be invaluable to those about to enter on investigational work with radioactive or stable isotopes, and to those with some experience in this field the articles will certainly be of interest.

Vitamine und Vitaminetherapie

Prof. Dr. Med. EMIL ABDERHALDEN, director of the physiological chemical institute, University of Zurich; Prof. Dr. Med. GEORGES MOURIQUAND, director of the Children's Hospital, University of Lyons. Berne: Huber. 1948. Pp. 408. Sw. fr. 28.

THIS is the first of a series of therapeutic handbooks to be published under the general editorship of Prof. T. Gordonoff of Berne. The object of the series is to provide, in nine relatively small volumes, each written by two or three experts, authoritative modern information. Professor Abderhalden has written the historical and biochemical part of this volume (188 pages) and Professor Mouriquand the clinical section. The first part carries a historical survey followed by more detailed treatment of each of the vitamins of the B complex, the fat-soluble vitamins with their provitamins and analogues, and the essential fatty acids and amino-acids. This section is copiously illustrated by photographs and structural formulæ, and closes with tables of vitamin food values and human requirements. In the second part Mouriquand distinguishes exogenous and endogenous—or as we would say "conditioned"—deficiencies due to diseases of the

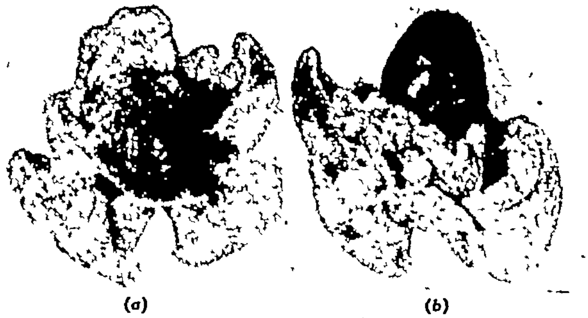

Fig. 1—Normal guineapig lungs and heart, showing collapse of lungs after removal from chest: *a*, anterior view; *b*, posterior view.

Group 2 consisted of four guineapigs which we injected intraperitoneally with 2 ml. of serum despeciated by our method of alkalinisation and heating, followed 30 days later by 5 ml. The results were as follows:

Guineapig 1: death from asphyxia in 2¹/₂ hours.
Guineapig 2: no effect.
Guineapig 3: slight effects with recovery.
Guineapig 4: death in typical anaphylaxis within 10 min.

Necropsy in the two guineapigs which died showed a picture of anaphylactic death with gross overinflation of the lungs, these did not collapse after the pleural cavities were opened and indeed remained inflated after they had been removed from the thorax.

Thus we demonstrated conclusively that our method of preparation of the serum did not destroy the antigenic properties of the bovine serum. We had failed to produce a despeciated bovine serum by alkalinisation and heating to 72°C. We had produced instead a substance composed of one grossly abnormal protein, with an osmotic tension only a fifth of that of the original bovine serum, which was still antigenic and capable of producing anaphylactic death in guineapigs. Whatever despeciation is produced by Edwards's formol-ammonia-heat method it is not due entirely to the heating as Edwards thought. Therefore despeciation by Edwards's method is probably du in part to the formolisation and in part to heating

RESULTS OF REPEATED INJECTIONS OF DESPECIATED BOVINE SERUM IN GUINEAPIGS

Guineapig no.	First injection (2 ml.)	Interval (days)	Second injection (5 ml.)	Interval (days)	Third injection (5 ml.)
1	Nil	35	Nil	59	Slight anaphylaxis
2	Nil	35	Slight anaphylaxis	59	Nil
3	Nil	35	Slight anaphylaxis	59	Nil
4	Nil	35	Nil	59	Died of pseudo-tuberculosis
5	Nil	35	Nil	59	Died of pseudo-tuberculosis
6	Nil	35	Nil	59	Nil
7	Nil	40	Nil	39	Nil
8	Nil*	..	..	..	..
9	Nil	40	Gross anaphylaxis	39	Nil
10	Nil	40	Nil	39	Died in well-marked anaphylaxis
11	Nil	40	Slight anaphylaxis	39	Nil
12	Nil	40	Nil	39	Nil
13	Nil	40	Nil	39	Nil
14	Nil	40	Gross anaphylaxis	39	Slight anaphylaxis
15	Nil	40	Nil	39	Well-marked anaphylaxis
16	Nil	40	Nil	39	Nil
17	Nil	40	Nil	39	Nil
18	Nil	40	Nil	39	Nil

* Died after 1st injection, with old infarcts in liver, probably from old age.

Group 3 consisted of eighteen guineapigs injectin repeatedly with formol-ammonia-heat-prepared serum The accompanying table shows that anaphylaxi developed in eight of the eighteen guineapigs; that i was of gross and undoubted nature in four guineapigs and that one guineapig (no. 10), died in 45 min. i well-marked anaphylactic shock. Necropsy reveale undisputed evidence of anaphylactic death with gro inflation of the lungs (compare figs. 1 and 2).

That only one of eighteen guineapigs died show that serum treated by Edwards's method loses som antigenicity, carrying a lessened risk of producin anaphylaxis in guineapigs. Nevertheless these exper ments show that it can still produce anaphylaxis an even anaphylactic death.

The guineapig is, of course, far more susceptible anaphylaxis than man; but one cannot overlook th fact that, though such serum has been used without mi hap in many hundreds of patients, its antigenicit and power to promote anaphylaxis are not complete destroyed by Edwards's method, and the potenti danger still remains. With extensive administration this serum to man, anaphylaxis will be seen Cauti should be exercised in its further use

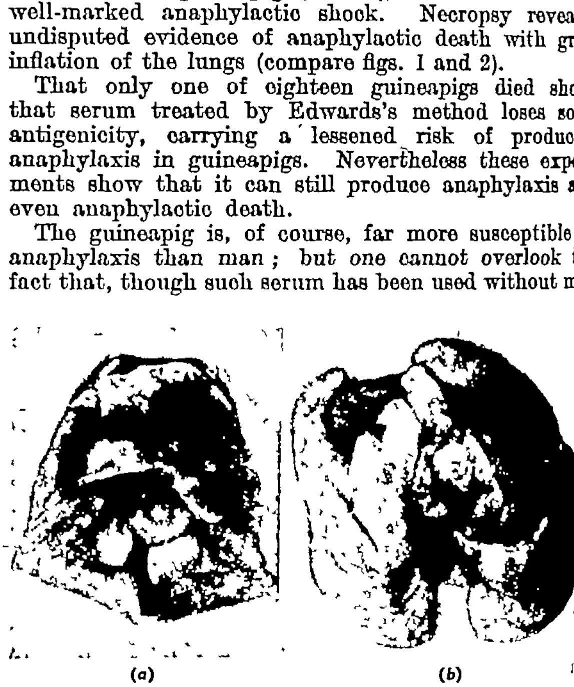

Fig. 2—Guineapig lungs removed from chest after death in well-mark anaphylaxis, showing maintained inflation of lungs due to bro spasm: *a*, anterior view, *b*, posterior view (same reduction as fig. 1).

SUMMARY

The degree of destruction of specificity secured Edwards's method of despeciating bovine serum is n due entirely to heating but to the formolisation a heating combined.

The specificity of the serum and its power of produci anaphylaxis are not completely destroyed by Edward method, and remain a potential danger in its use as substitute for human plasma.

Any process likely to remove effectively the specifici of bovine serum is likely so to reduce its osmotic effec as to render it unsuitable as a substitute for plasma f administration to man.

I wish to thank Dr. R. A. Kekwick and Dr. E. F. McCarth of the Lister Institute of Preventive Medicine, for the electr phoretic, ultracentrifuge, and osmotic-pressure reading Mr. W. Lee, of the central photographic departmen University of Liverpool; and Mr. Harold Nevin, technicia in the department, for valuable assistance.

THE LANCET

LONDON: SATURDAY, OCT. 16, 1948

First Quarter

GENERAL practitioners in the National Health Service have now received their first quarterly payment. Few have read the figures on their cheques with any satisfaction: most have felt that the work already done (to say nothing of busier quarters to come) deserved greater reward. As remuneration is calculated on the basis of an 18*s*. capitation fee for 95% of the population, and as it was unlikely that in the first three months so many as 95% would register, many doctors expected the first quarter to yield a comparatively high per-capita payment. Yet in most areas it has been less than 4*s*.

Several factors have contributed to reduce the amount. In the first place, the first four days of July, which came before the appointed day, were not included: and four days is almost 5% of a quarter. Secondly, no payments have been made during this quarter for temporary residents: credits accruing from these will be paid in next quarter's cheque. More importantly, the executive councils, being still unaware of their final commitments, have generally erred on the side of caution in making the first interim payment; to cover later eventualities they have kept something in reserve which will not be distributed until the final settlement next year. By that time the position should be clearer. It is known, for example, that there has been a considerable duplication of names, chiefly through form E.C.1 being forwarded in respect of patients already included in old panel lists; and until each form is checked and cleared some inflation is bound to persist. Again, the number of likely claims for treatment of temporary residents cannot be exactly foretold; nor has the total of mileage points claimed yet been calculated. A margin must be left for all of these, and each margin further reduces the amount of the pool available for initial distribution. Calculations of this type always had to be made before National Health Insurance cheques could be paid, and, once the numbers of the insured population in an area had become relatively stable, no great difficulties arose, and no inordinate balance had to be kept back for final distribution. But there remains one problem where no precedent can be quoted and where the needs and the decisions have varied widely from area to area. This is the problem of the "basic salary," or fixed annual payment. So much has the demand for this payment varied, and so little has general guidance been possible, that executive councils have had to make their own arrangements: and where they have thought fit either to grant a high proportion of fixed payments, or to put into reserve an appreciable sum for the eventual discharge of these payments, the remaining capitation fee has been proportionately depressed.

The right of a doctor to be remunerated in part by fixed annual payment has been progressively modified. The Minister of Health originally intended such payment to be universal; but the profession successfully opposed his wish to pay everyone partly by basic salary, and Mr. BEVAN eventually agreed that the fixed payment should be made only to those doctors who opted for it. When doubt arose whether such an arrangement would work fairly in the absence of restrictions, he accepted the British Medical Association's proposal that the fixed payment should not be made without specific approval of the local executive council: and after consultation with our representatives he indicated to executive councils certain categories of doctors to whom it might most justly be granted, including the doctor starting a new practice, or working up a small one, and the doctor unable, through age or ill health, to do as much as in the past. Little exception could be taken to extra help being offered to any or all falling into these categories, but the Minister went further when he suggested that the fixed annual payment might be made wherever "a doctor's income can be shown to have dropped substantially as a result of the new service involving an element of hardship." It is this last proviso, and its different interpretation by different executive councils and local medical committees, that has given rise to widely differing decisions. Some of the councils have asked that the doctor claiming the payment shall reveal his total income from all sources, and this has led to the charge that the Government are insisting on a means test for members of the profession.

Actually it is the doctors themselves who have demanded this income declaration from their colleagues, for the very pertinent reason that it is they who are paying from their own moneys the basic salaries that are granted. In putting forward the universal fixed payment the Minister arranged for it to be a first charge on the local pool of money from which the local executive council would pay the practitioners in its area. This would have been reasonably fair. It would in effect have provided a kind of sliding scale giving a higher average capitation fee for the man with the smaller list. But when the universal fixed payment was abandoned, and an optional one was substituted, it was decreed that the capitation fee for those doctors asking for the payment should be reduced by a seventh, and it became evident that any doctor with less than about 2200 patients would draw more from the pool if he was given a fixed payment than if he was not. Seeing that he obtains this extra amount at the expense of his colleagues with the larger lists, many local medical committees have refused to support applications unless they are satisfied that there is good reason for the claim. Some insist that the claimant shall reveal all sources of income and prove actual financial hardship; they treat the claim as a request for charity and they impose a means test. In present circumstances it is certainly permissible to say that no claim should be granted unless the whole picture of the doctor's practice is known. Obviously it would be unnecessary and unfair to subsidise the income of a junior partner, with a short list, if he was mainly employed in helping one or more senior partners with long lists, for each of whose patients full gastro-intestinal tract, the liver, and other organs, and discusses the outstanding clinical diseases due to the specific vitamin deficiencies, and their treatment.

The book is good and moreover has balance, which might well have been lacking in the joint work of a German biochemist and a French clinician. The first part is on the whole well documented, though with an understandable bias towards German and Swiss publications. No volume of this size can claim to mention everything connected with the subject, but it is a little surprising to find vitamin D_2 dismissed so summarily, and no reference made to the work of Harris and Moore in the late 'twenties on hypervitaminosis D. Phytic acid is not mentioned at all, and the section on resistant rickets and osteomalacia is distinctly dated, showing no grasp of the recent Anglo-American work on treatment. There are none of the vivid clinical descriptions which one expects of a French writer, and some of the photographs are disappointing. It is, however, easier to criticise than to create, and those who read German will value this book, since parts of it are probably better than anything current in English.

Lehrbuch der inneren Sekretion

F. VERZÁR, professor of physiology, University of Basle. Liestal: Ars Medici Lüdin. 1948. Pp. 609. Sw. fr. 52.

Professor Verzár has written a comprehensive and authoritative textbook on endocrinology primarily from the physiological point of view. The bibliography is full, and especially valuable to the English reader because it contains many Swiss and Continental references with which he may not be familiar. The treatise is up to date and is a reliable reference work. It can be recommended to those who wish their library of orthodox endocrine publications to be complete.

Science in Progress

(Fifth series). Editor: GEORGE A. BAITSELL. New Haven: Yale University Press. London: Oxford University Press. 1948. Pp. 353. 27*s.* 6*d.*

THIS volume can be classified under the heading of Popular Science for the Scientist. The ten essays in it, reprinted from recent issues of the *American Scientist*, are too technical to be understood by the complete layman, but are of just the right level of comprehensiveness and precision to appeal to scientists in other fields. Most of the contributors' names are household words in the medical profession: Peyton Rous, writing on tumours; G. W. Beadle, on biochemical genetics with special reference to the bread mould neurospora; Michael Heidelberger on complement fixation; C. C. Speidel on the study of living cells; and Herbert M. Evans on the hormones of the anterior pituitary gland. Other essays (on the interior of the earth, for example, or the betatron) are written by authors equally well known in their fields. The standard of writing is high and the essays are well documented. It is a first-rate book, and can be particularly recommended to those whose stomachs revolt at the sort of popular science which contrives to be at once patronising, pompous, and imprecise.

Bergey's Manual of Determinative Bacteriology

(6th ed.) Editors: ROBERT S. BREED, New York State Experimental Station (Cornell University); E. G. D. MURRAY, McGill University, Montreal; A. PARKER HITCHENS, University of Pennsylvania, Philadelphia. London: Baillière. 1948. Pp. 1529. 82*s.* 6*d.*

BACTERIOLOGISTS will welcome this new edition of "Bergey," whose publication in the United States we have already mentioned (1948, i, 952). Nevertheless, those accustomed to our binomial system of bacteriological nomenclature may turn the pages a little anxiously; for in previous editions bacterial species have often been moved from one genus to another, adding confusion to a difficult subject. Seeking familiar names, we find that *Staphylococcus aureus* now has the clumsy designation *Micrococcus pyogenes* var. *aureus*; but most British bacteriologists will be glad that *Eberthella typhosa* has gone, and they may even agree that *Salmonella typhosa* is less likely to cause confusion with typhus than *Salmonella typhi*. There are many similar changes, and even if we regret unstable nomenclature we must recognise the new if we mean to rea contemporary American and English literature. For th specialist there is something fresh in the presentatio of the relationships of every genus, and the number o species has increased from 1335 in the fifth edition t 1630 in this. Particularly valuable is a new index statin which organisms have previously been recorded from particular source. The orders Rickettsiales and Viral are in supplements: the viruses under the subgrou bacteriophage, plant, and animal viruses compris 13 families, 32 genera, and 248 species. Taxonomy becoming increasingly important, and the numero contributors to this edition have done important scientif work.

Investigations on Agonal Acidosis

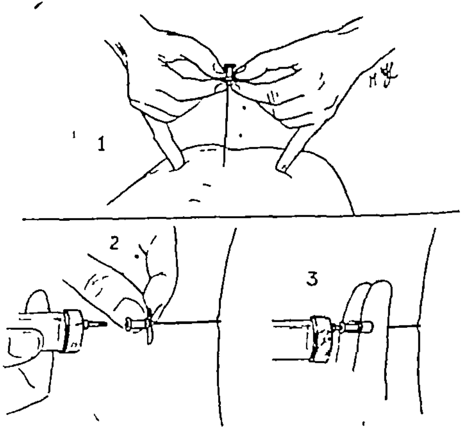
IB FABRICIUS HANSEN, translated by HANS ANDERSE M.D. Copenhagen: Poul Branners. 1948. Pp. 135.

THIS short book gives an account of the biochemi changes during the period immediately preceding deat in man. On some 38 moribund patients Dr. Hansen h carried out examinations of the pH, carbon dioxid chloride, urea, protein, hæmoglobin, oxygen, creatin guanidine, amino-acids, lactic acid, pyruvic acid, seru sulphate and phosphate, total acetone bodies, total bas and non-protein nitrogen. Mean values of the vario results are recorded, with full case-histories of ca patient and a large bibliography. The main findings a a fall in blood pH immediately before death, with increase in plasma lactic-acid content, which sometim is very great. Most cases showed a terminal azotæm with increased urea, amino-acid, and creatinine nitrog values. No relation has been demonstrated between t azotæmia and the fall of pH.

New Inventions

A SPINAL NEEDLE

THE main object of the modification here describ is to allow lumbar puncture to be performed without t point, shaft, or hub of the needle being touched. T needle is held throughout by two flanges which proje at right angles at the junction of the hub and shaf A two-handed stance allows counter-pressure to b exerted by the little fingers on either side of the spin column (fig. 1); in this way the needle is steadied and it direction controlled more easily.



Figs. 1–3.

If a spinal anæsthetic is to be given, the needle is hel in situ by a flange while the syringe is being attache (figs. 2 and 3). By this means fingers are kept away fro both the nozzle of the syringe and the hub of th needle.

The needles are obtainable in various lengths from $2^{1}/_{2}$ to 4 in., from the Longworth Scientific Instrument Co. Ltd., Thames Street, Abingdon-on-Thames, Berks.

Oxford.

nty-four hours after infection. In two experi-nts mice were given a single dose by mouth before fection, and more than half survived though all ntrols died. The drug is said to be "strikingly n-toxic" in mice and monkeys. Tests have been ne on monkeys infected with poliomyelitis of human igin but the results are not reported. Apparently benosulphazole does not react with the SK virus vitro but inhibits its growth in tissue-cultures. It argued from this that its action is on the cell, not the rus. Surely this is an odd conclusion, for various ugs inactivate bacteria only during their active owth and viruses can only grow in living cells. particularly important point is that the drug's tivity is inhibited by *p*-hydroxybenzoic acid (the ect of *p*-aminobenzoic acid is not stated).

The picture in *Time*[3] is copied from an electron otomicrograph shown by E. De Robertis and O. Schmidt of the Massachusetts Institute of chnology at a meeting in Canada. This photograph a piece of the sciatic nerve of a rhesus monkey is d to show the poliomyelitis virus in the nerve. rlier work has demonstrated the remarkable ectivity of this virus for neurons and suggested t it probably spreads centrifugally within the oplasm of peripheral nerves. Bodian and Howe,[4] ng the immersion method of inoculation of the t end of the sciatic nerve in the rhesus monkey, owed that after a latent period of eleven hours the us progressed up the nerve at about 2·4 mm. per r. They tested for the presence of virus at different els by inoculating nerve intracerebrally into nkeys. According to the report, De Robertis Schmidt have observed bodies in poliomyelitis-d sciatic nerves of the monkey which were not a healthy nerves; and serial pictures revealed ent of these bodies up the nerve at the same as Bodian and Howe found for live virus. It long been recognised that the virus causes gible disturbance of axonal function as it moves g the nerves, but exactly how it progresses has been understood. These new revelations of the tron microscope suggest that the virus flows ively along the exoplasm. Most of the previous dies of the size and shape of the poliomyelitis us by filtration and the electron microscope have n on purified preparations of human stool or nal cord. According to the filtration experi-nts, the virus either is a sphere about 8–17 mμ diameter, or if it is asymmetrical, has a cross-tion of this dimension. Both American[5] and edish[6] workers have found rod-shaped particles 5–35 mμ in diameter in purified preparations of fected human stools and spinal cords, but they have nd similar particles in the stools of normal children ing in non-epidemic areas. The preparations from healthy" stools were not infectious for monkeys, ich suggests that the rod-shaped particles in both parations are flagella of bacilli or some other traneous matter to which the virus may be firmly tached in the infected specimens. Recently Loring al.[7] have concentrated the Lansing strain of virus obtained from infected cotton-rat brains in sufficient quantity to provide an antigen for a complement-fixation test. These advances in physicochemical methods of purification should eventually supply a preparation which will unravel this mystery.

Lymphocytes and the Adrenal Cortex

In discussing the formation and destruction of lymphocytes earlier this year[1] we described the evidence brought forward, particularly by Dougherty and White, in support of the view that adrenal cortical hormones control the process of dissolution of lymphocytes, that this dissolution leads to the liberation of γ-globulin, and consequently that the adrenal cortical hormones can be said to be concerned with antibody liberation and possibly with protein metabolism. The hypothesis was received rather coolly, and more recent work has been in several ways contradictory. Valentine et al.[2] set out to observe the effect of adrenocortical hormones on the number of lymphocytes appearing in the thoracic duct lymph of cats. They were careful to use adrenal cortex extracts and not the synthetic desoxycorticosterone, since it has been shown that the so-called "sugar" corticosteroids (i.e., those with the oxygen at C_{11} and C_{17} positions) are the important ones for hæmatological effects. Nevertheless the expected diminution of lymphocytes was not found—in fact there was no significant effect at all.

There seems to be no doubt that adrenocortical hormones produce macroscopic and microscopic involution of lymphoid tissue. It is also clear that injurious stimuli cause similar changes, and that the effects do not appear in adrenalectomised animals. There is much evidence to show that adrenal cortical hormones will produce a lymphopenia in normal animals. Most of the results were obtained in rats or mice, which normally have 60–90% lymphocytes in their blood compared with 20–40% in man. However, there have been some significant findings in man. Thus Hills et al.[3] gave a single dose of 25 mg. of pituitary adrenocorticotrophin to 8 normal persons and 38 patients with various diseases but all with intact adrenals; a definite reduction in the circulating lymphocytes followed. A similar course given to 26 patients with Addison's disease produced very variable results—the lymphocytes in the blood showed anything from a 31% increase to a 28% decrease—but a dose of 17-hydroxycorticosterone caused a definite lymphopenia in every one of 5 patients. It was also noted that if adrenocorticotrophin is given regularly for some days the lymphopenia disappears in 24 hours and may give way to a lymphocytosis; Hills and his colleagues have no explanation for this result. On the other hand, the evidence that patients with insufficient adrenal cortex, as in Addison's disease, have an increase in circulating lymphocytes is highly equivocal. For instance, Baez-Villaseñor and others[4] studied the blood picture in 100 patients with Addison's disease. They set the normal high level at 40% lymphocytes, with a normal leucocyte-count, and by this criterion 16% of their 28 untreated

capitation fees were being drawn. It is to prevent such an abuse that some executive councils have ruled that a basic salary cannot be granted to one partner unless the other partners also accept this form of payment. A practitioner can fairly say: "I prefer to limit my list of patients to a number which enables me to give unhurried service to them; in return for this I ask that I shall be paid proportionately more per patient; and so I claim the fixed payment." Before he does this he should be prepared to reveal the whole pattern of his practice so that the council may be assured that the time saved by having a shorter list can in fact be devoted to his panel patients, and will not be absorbed by paid appointments at clinics or hospitals, or by attention to an excessively large proportion of private patients. On the other hand for an executive council to declare that the doctor with private means or a wealthy wife shall be excluded from a method of payment that could legitimately be claimed by another practitioner, doing identical work, is wholly improper. The basic salary should not be regarded as a sort of alms, provided obligatorily by the busier doctors, to be doled out to the deserving poor among their colleagues, but as a means of obtaining sound conditions of practice, for doctors and patients alike.

At the moment conditions of practice are not conspicuously sound, and it would be useful to have an assurance that defects will be quickly remedied where necessary. As things stand today, the general practitioners are certain that their first payment in no way fulfils the promise of the first Spens report, and few believe that adjustments in coming quarters, when all errors and omissions have been rectified, will bring their remuneration into line with the Spens recommendations. Moreover it has become painfully obvious that a universal capitation system, unless more carefully compensated, works to the disadvantage of many of the doctors with the highest standard of practice.[1] Difficulties and anomalies of this kind were bound to arise, and some of the problems will solve themselves; but we trust the Minister will recognise the need for an immediate review of the subject as a whole, either with the Negotiating Committee or by the Whitley Council. Such a review should cover not only the amount of remuneration but also the sources of its various fractions. There are strong reasons why the sums that are not paid universally—e.g., the mileage, the inducement payment, and the fixed annual payment —should come from a fund kept separate from the main capitation pool. The inducement fund is already a separate fund; the mileage used to be, and could be again. The fixed annual payment could, with even greater advantage, also be kept separate. If this were done, it could be financed partly from the main pool of those capitation fees (a seventh of his total) which the doctor foregoes when he opts for the fixed payments. But the doctor with the long list would no longer be able to complain that his capitation fee was being depressed for the benefit of colleagues unable or unwilling to care for so many patients.

A bad start has been made, but it has at least had the advantage of revealing possible causes of continuing dissatisfaction. These causes being revealed the cure should not be difficult to find. It is ver desirable that discussions should be successfull concluded in time to ensure that practitioners deriv due satisfaction from the cheques they will receive i the New Year.

News about Viruses

In the United States, where this summer has seen high though fairly localised incidence of poliomyeliti the disease is now receiving nearly as much publi attention as cancer. One result is that news experimental findings are appearing in the lay pre before publication in the scientific journals. Th tendency, however, is not confined to America or t poliomyelitis, as a peripatetic correspondent[1] late noted. No blame attaches to the research-workers, wh as a rule have merely read a preliminary paper o their subject to a learned society; and certainly not t the press, which is there to supply what its reade demand. If there must be a moral it is that scienti journals are apt to be more cautious than enterprisi in gathering news. The fact remains that we in th country first learnt of phenosulphazole, a sulpho amide active against viruses, from a press notice issu by Columbia University; and our first view of t poliomyelitis virus spreading up a peripheral ner was in the pages of *Time*.

The activity of some antibiotics and sulphonamid against the large viruses of the psittacosis-lymph granuloma group is now established, and there ha been hints and suggestions in recent publications the possibility of finding agents active against son of the main body of viruses outside that group. Th work on phenosulphazole, done by Dr. SubbaRo (who died in August) and his colleagues,[2] may provi the much-needed lead to guide us into this big fiel The new drug is the sodium salt of N-(2-thiazoly phenolsulphonamide; trade name 'Darvisul.' I was one of many compounds developed at the Cal and Lederle laboratories in 1947 and "showe promise," apparently against the virus of wester equine encephalomyelitis. During the last ye it has been tested against "poliomyelitis." Here word of caution is needed. The virus workers Columbia University do not agree with those in mo other laboratories as to the limits of the term "poli myelitis virus." SubbaRow, et al. have studied th Columbia-SK strain, which infects various roden and differs from orthodox poliomyelitis viruses in it high infectivity by the intraperitoneal route and i other ways. Most workers believe it is of cotto rat or mouse origin and not closely related to huma poliomyelitis though a member of the same broa family group. The protocols show a high rate o survival in infected mice injected with 4–8 mg. o phenosulphazole two or four times a day over fiv days. A survival-rate of 100% was obtained onl where the mortality in controls was well under 100% but in one group 17 out of 20 treated mice survived fo fourteen days where all of 20 controls died. Numerou recorded tests gave similar results. Surviving mice were subsequently immune to reinoculation. Such results were obtained when treatment was begun

additions to the auxiliary fund; and the report records a gift of £450,000 by Captain Oliver Bird for rheumatism and other medical research. In the trustees' introductory words is:

"The welcomed increase of State support for learning and research does not lessen the need for voluntary enterprise: neither does it decrease the importance of alternative sources of support if the principle—fundamental to a free and democratic society—is to be upheld that 'there should be room for more than one opinion and for more than one means of putting that opinion to the test.'"

MEDICAL FILMS

The three medical film meetings held on Oct. 8, 9, and 11 by the Scientific Film Association[1] in conjunction with the International Scientific Film Congress in London made it clear that too many recent productions are comparable to unrevised laboratory notebooks and not prepared lectures or articles. On Oct. 8 there was a reasonably good film from Australia showing neurological sequelæ of starvation; this was followed by a Danish one on the clinical examination of syphilitics; then by a Belgian film which was difficult to follow fully, and by an American film on the toxic effects of streptomycin which wasted time on introductory sequences and on demonstrating nystagmus which was not there. Dr. Margaret Fries's film on the psychological implications of observations of behaviour during a (pædiatric) clinic visit showed what a wonderful subject this is for a teaching film, but did not quite overcome the difficulties it presents. Mr. E. Gwynne [illegible]'s film on the behaviour of the orofacial musculature in children opened up new and more intelligent diagnostic and therapeutic approaches to the problems of "adenoidal" and mouth-breathing children. Two other films illustrating cases of chorea and Friedrich's ataxia, were approved for their brevity and directness; the omission of unnecessary introductory shots and distracting furnishings in the backgrounds, and because [illegible] everything in the commentary was illustrated in the films. The absence of choreic movements during sleep, a fact that clinicians have usually to take on trust, was well demonstrated, and the shots of the child after recovery gave the viewers an interest in her as a person as well as a case. This admirable new venture by the Wellcome Medical Museum should certainly be expanded.

Next day Mr. R. McV. Weston spoke on cinemicrography and showed four examples. The first was an excellent twenty-year-old Canti film of cells in tissue culture: the other films showed a progressive improvement culminating in the film of osteoclasts made by Mr. Weston in collaboration with Dr. Norman Hancox, of Liverpool University. The evident possibilities of this skilled technique should be exploited for larger audiences. Teachers of biology and physiology would welcome a fifteen-minute film on the behaviour of living cells in normal blood.

The lesson of the first day's meeting was that badly photographed and badly edited films cannot tell a story; but the moral to be drawn from the discussion on the second day was that good photographic technique is not enough. The American Medical Association centenary film, *The Medical Motion Picture*, was followed by a recently finished British film, *Subtotal Hysterectomy*, shown as a text for discussion. The lighting and colour were first-class, but the case was an unfortunate choice for the tumour was so large that it was difficult to see the other organs; only once was any detail of surgical technique shown, and possible difficulties were not emphasised. The criticism that this operation is or will be rarely done led to the expression of a widely held view—that the potential audience is too small to justify the making of postgraduate surgical films, in view of the urgent need for improving the teaching of students and nurses. The meeting ended with the film *Introduction to Acute Inflammation*, made by Dr. Beckett, Dr. Hansell, and Dr. Moller when they were students at the Westminster Hospital. This film uses diagrams, colour, and microscopy, and is a good instrument for teaching.

The last meeting opened with an American film on peptic ulcer, followed by a short cartoon film by Giles, *Cautionary Tales about Sepsis*. Mr. E. Fife Clark, public relations officer to the Ministry of Health, outlined past and present films from his ministry and discussed the part the film can play in health education. Miss Mavis Englefield of the Queen's Institute of District Nursing, introducing the U.S. Navy film, *Bathing the Bed Patient*, made a plea for simple nursing training films for mothers who like to look after their sick and would like to do it better. Dr. Stanford spoke on the value of short films, and several of these were shown—on the foramen ovale, a Dutch film on D.D.T. poisoning, an English film on the Aschheim-Zondek test, another showing a case of Sturge Weber syndrome (ending with the child sitting on Dr. Parkes Weber's knee), and one telling nurses how to put on a mask. Dr. Bloemensthal, of Holland, introduced a film he has made on the development of the peritoneum—an ideal subject for animation.

The meeting brought out once again the value of polished technique, to ensure that the audience's interest is in the content of the film,[2] and the importance of having a clear idea of what the film is to say and to what audience. It is good to hear that the S.F.A. are arranging that some, at least, of the films seen will be available in this country.

THE NAMES OF BACTERIA

The complexities of bacteriological classification can only be guessed at by the student who has to follow his textbooks, or by the clinician who must grasp the gist of laboratory reports; but the present multiplicity of authoritative nomenclatures is a trial for both of them. On one side of the Atlantic we have the radicalism of Bergey's Manual[3] (reviewed on p. 612), which has not hesitated to lay hands even on such an old enemy as *Staphylococcus aureus*; moreover its sixty contributors, like their predecessors, seem to have ignored much of the work done outside the American continent. On the other side the Medical Research Council follows a more conservative path in the new list of species[4] maintained in the National Collection of Type Cultures at Elstree, Herts. In general the List follows the familiar nomenclature of Topley and Wilson,[5] so that *Salmonella typhi* has not suffered a sea change, à la Bergey, into *S. typhosa*.

On points of detail, medical bacteriologists may express surprise and regret that neither publication recognises the species *Bacillus mesentericus* and *B. vulgatus*: in the past the name mesentericus has been given to different organisms, but most strains are now regarded as either *B. pumilus* or *B. subtilis*. *B. anthracis* retains its identity in spite of Nathan Smith's[6] view that it is a pathogenic variety of *B. cereus*. Synonymy is common in the genus Clostridium: the List prefers *welchii* to the Manual's *perfringens*, though neither is valid if the Bacteriological Code is strictly followed. Bacterium is used in the Manual as the generic name for gram-positive and gram-negative non-sporing rods of uncertain taxonomic position; in the List it is used in italics for coliforms (*Escherichia* and *Aerobacter* of the Manual) and related intestinal organisms, and in roman type patients and 48% of the patients maintained on desoxycorticosterone acetate had a lymphocytosis; but the "average" figures given for these groups show that the 40% level has only just been exceeded and most of the counts would hardly be regarded as abnormal. Others have had similarly unconvincing results.

---

The severest criticism has fallen on that part of the theory which connects the dissolution of lymphocytes with the release of globulin antibodies. Li and Reinhardt[5] gave adrenocorticotrophin to rats and found that the plasma globulin actually decreased, but the albumin increased; Gjessing and Chanutin[6] report similar findings; Houghton et al.,[7] using cats and rabbits, were also unable to confirm Dougherty and White's findings. Again, it has been noted that increased serum globulin is not found in human diseases associated with lymphatic hyperplasia; Nitske and Cohen,[8] for example, found no significant alteration in serum proteins in 12 patients with lymphatic leukæmia. Fagraeus[9] denies that lymphocytes have anything to do with antibody formation and points out that the changes in lymphocytes brought about by adrenocortical hormones occur in le
12 hours, whereas most antibody formatio
place 48 hours after appropriate stimulation.
plasma cells, she says, that are important for a
formation, and there is good evidence no
plasma cells are derived directly from r
endothelium and are not modified lympl
Fagraeus carried out *in-vitro* experimen
isolated fragments of rabbit spleen; she fou
there was always more antibody in red pulp
white pulp containing splenic follicles (mal
bodies), and that the capacity of the red pulp
antibodies varied with the number of plasm
especially immature types that were present

The idea that the dissolution of lymphocytes
by adrenal cortical hormones is concerne
globulin production in general and antibody
in particular must therefore be regarded as
proven." This is a pity because we have s
firm information on the function of the lymp
But such contradictions should remind us to
mind the possible fallacy of assuming that
brought about by artificial and considerable
of hormone concentrations represent the
mechanism of control; we are in fact faced w
old difficulty of deciding whether observed
are physiological or toxicological.

Annotations

MEDICAL RESEARCH COUNCIL

Viscount Addison, M.D., has joined the Medical Research Council as chairman in succession to Lord Balfour of Burleigh. Others whose appointments to the council were announced this week are: Sir George Schuster, who succeeds Sir William Goodenough as treasurer; Sir Frederic Bartlett, F.R.S., professor of experimental psychology in the University of Cambridge; Sir Howard Florey, M.D., F.R.S., professor of pathology in the University of Oxford; and Mr. Geoffrey Jefferson, F.R.C.S., F.R.S., professor of neurosurgery in the University of Manchester. The other members of the council are: Group-Captain C. A. B. Wilcock, M.P., Prof. P. A. Buxton, M.R.C.S., F.R.S., Prof. Sir Alexander Fleming, F.R.C.P., F.R.S., Prof. C. A. Lovatt Evans, F.R.C.P., F.R.S., Prof. R. A. Peters, M.D., F.R.S., Prof. J. H. Gaddum, M.R.C.S., F.R.S., Prof. H. P. Himsworth, F.R.C.P., and Sir Edward Mellanby, F.R.C.P., F.R.S. (secretary).

NUFFIELD FOUNDATION

Two of the objects of the Nuffield Foundation are well known to doctors. These are "the advancement of health" and "the care and comfort of the aged poor." *But there is a further aim—namely, "the advancement* of social well-being"; and under this broad canopy the third report[1] records new grants for work on such widely differing topics as agricultural policy and the development of the reflecting microscope. In the field of the social sciences support is promised for a study of group relations and an investigation into the social factors of town-planning.

> "Town-planning in the past," the report observes, "has taken account of sanitary needs, natural features, and æsthetic considerations, and has reached the concept of the 'master plan'; but *knowledge of the social and economic* trends which should provide the real basis for continued planned development consists mainly in wisdom acquired after the event."

The foundation is also supporting a study of the
classes, with special reference to their recruitm
intricate system of which little is known. Recruit
another sort is to be examined by Prof. Aubre
at London University's Institute of Psychiatry. P
Lewis is undertaking a long-term study of un
candidates—accepted and rejected—with the
determining: (1) to what extent the existi
familiar practice of selection agrees with the re
psychological procedures; (2) whether, in those ac
academic or psychological assessment agrees bett
the students' examination results and later perfor
and (3) what happens to those rejected, and how f
subsequent success or failure could have been pr
from the results of the psychological tests.

CONDITION OF CHILDREN IN WESTERN GERMANY

A. P. MEIKLEJOHN
M.A., B.M., B.Sc. Oxfd
LECTURER IN NUTRITION, DEPARTMENT OF MEDICINE, UNIVERSITY OF EDINBURGH

LITTLE has been published on medical conditions in -war Germany. Newspaper reports have been scanty often conflicting. Consequently it has been difficult anyone outside the country to get a clear impression the state of health of the people. Particularly, a great l of doubt and anxiety must exist about the health the children. This paper, based on observations made ing two recent visits to Germany,* has been written the hope that it may help to relieve such uncertainties. is does not claim to be a precise scientific study but ely sets forth the observations and conclusions of person who has recently seen and examined many man children.

Whenever health in Germany is discussed, it has me usual to think first of nutrition. It is therefore ll to begin with a short account of the population and origin of its food.

The present total population of the combined British-S. zones, excluding Berlin, is about 41,300,000. The ulation of the French zone is about 5,000,000. Of population in the British-U.S. zones 80% are "non-suppliers" and therefore depend on the rations. Of e, about 9,000,000 are children up to the age of 18. re are about 1,000,000 children up to the age of 18 the French zone.

fore the war the area now comprising the British U.S. zones produced about two-thirds of the food to provide its whole population with an average calories per head daily. But then the population ly 34,000,000. Now there are 7,250,000 more to be fed (mainly refugees from the east). Con-ly more than half the food for this population imported, even though they eat less.

1939 the crop of bread grains in the combined ish-U.S. zones was about 5,700,000 tons. By 1946 had fallen to 3,450,000 tons, mainly through lack of ilizers. The potato crop was about 17,500,000 tons re the war but had decreased by 6,000,000 tons in 6. Further, before the war about 1,000,000 tons of d grains, 1,000,000 tons of potatoes, and 400,000 of sugar used to come from the east—and this no er comes. All this explains why it was necessary import about 4,000,000 tons of bread grains into the ish-U.S. zones in 1947. The actual deliveries from man farms to the market in the year ending June 30, 7, was 2,250,000 tons. Hence in 1946 and 1947 about thirds of the bread ration in the British-U.S. zones from imported grains. About the same proportion bread grains is imported into the French zone.

THE CHILDREN'S RATIONS

On the whole the children have received a generous re of the tremendous amount of food imported into zones. When supplies have been short, it has usually been the policy to meet the children's rations and workers' supplements first out of available stocks; whatever then remains has been distributed on the basic adult ration to the "normal consumers," of whom there are about 10,000,000 in British-U.S. zones who receive no additional supplementary rations of any kind.

The foodstuffs actually provided as rations to children in British-U.S. zones in May, 1948, are shown in the accompanying table. These rations have undergone very little change in the past two years. It will be noted that though these rations provide extremely little meat and fat they at least provide a good amount of milk for the younger children.

Milk.—Supplies have fallen off by about 30% since 1939–43. This is mainly because the German cow is producing very much less milk through lack of imported cattle-feed and because of the poor fodder crop of 1947. It is greatly to the credit of those responsible for the organisation of food distribution in Germany that the limited supplies of milk available have been successfully applied to the needs of young children. Inevitably, however, the older children have received less than their needs. Another unfortunate circumstance is that bad transport and cooling facilities lead to the distribution of much half-sour milk, especially in summer. In some places this undoubtedly contributes to the infant mortality.

Food in Addition to the Rations.—From the table it will be seen that, though the caloric value of the ration for children under the age of 3 years is adequate for their needs, above this age the ration becomes increasingly insufficient to meet energy requirements. For the older children especially, their health and nutritional state depend vitally on food obtained in addition to the rations. The sources of such additional food are as follows:

OFFICIAL MONTHLY RATION ALLOWANCES FOR CHILDREN IN COMBINED BRITISH-U.S. ZONES, MAY, 1948

Commodities (g.)	Age-groups (years)			
	Under 1	1–3	3–6	6–20
Bread	2200	3250	6600	11,000
Cereal products	2175	1500	1250	1100
Potatoes	4500	4500	9000	9000
Fat	375	330	330	330
Sugar..	1375	1000	1000	1500

School Feeding.—A school-feeding programme was begun first in the British zone and extended, in 1947, to the U.S. zone, following the recommendations of Mr. Herbert Hoover. In May, 1948, about 5,000,000 school-children in the two zones were receiving a snack of about 300 calories in school, on average five days a week. This snack generally consisted of a sweet "soup" of cereal and milk powder, or sometimes a salted soup containing meat extract and some fat, often served with a bread roll. The distribution is planned to cover the neediest children and is very well organised. It is universally appreciated by teachers, parents, and the children. In the French zone no similar programme is at present in operation, chiefly owing to shortage of supplies.

---

* I visited Germany in October, 1947, as a British representative on the Combined United States, British, and French Nutrition Committee, and again in May, 1948, as a member of a mission sent by the United Nations International Children's Emergency Fund, to investigate the condition of children in the three western zones of Germany. The views and conclusions expressed here are purely personal and do not necessarily reflect the official views of either of these bodies. The account of the food-supplies is based on conditions existing in May, 1948. I understand that the situation has considerably improved since then; the basic adult ration has been increased and more food is appearing on the open market as a result of the currency reform.

as a dump-heap for gram-negative rods that cannot be placed elsewhere. In neither case is the use of this generic term intended to be part of a systematic classification. There is an undesirable tendency, in both the Manual and the List, to put too much stress on the source of the organisms in determining their taxonomic position. This is an unhappy result of the division of bacteriology into watertight compartments—for example that of the medical worker who knows nothing of plant pathogens, and that of the plant pathologist unfamiliar with the bacteriological flora of polluted water.

The staphylococci are still to be found under the letter S in the List (instead of under *M* as in Bergey), but the List has adopted a new, and so far unexplained, classification for them. Ten years ago, Dr. Cowan,[7] who is curator of the National Collection, published a scheme in which coagulase production (which correlates well with toxigenicity) was used as the main criterion for the species *pyogenes*, and, as was to be expected, this is adopted in the List. Pigment is given taxonomic value only in the coagulase-negative strains; the specific name *aurantiacus* is used for the gold colony form to avoid confusion with the well-known *aureus*, now included in the species *pyogenes*.

An attempt is made in the Manual to include bacteriophages and viruses in a systematic classification of bacteria. Phagus, the generic name used for bacteriophage, is easily recognised, but *Tarpeia premens* (common cold), *Erro scoticus* (louping-ill), *Hostis pecoris* (foot-and-mouth disease), *Scelus recurrens* (herpes simplex), and *Borreliota variolæ* (smallpox) are not likely to be found in English writings for some time to come. British workers are not yet attempting to classify the viruses, since little or nothing is known of their "systematics."

AUREOMYCIN

PENICILLIN and streptomycin, effective as they are in many infections, still leave gaps in the antibacterial spectrum; so the search for new antibiotics goes on. A new one, described by B. M. Duggar of Lederle Laboratories, is aureomycin, derived from a strain of *Streptomyces aureofaciens* and effective against numerous gram-positive and gram-negative organisms, including streptococci of Lancefield groups A, D, F, and G, *Strep. fæcalis*, *Bact. pneumoniæ*, *Streptococcus pneumoniæ* types I, II, and III, *Hæmophilus influenzæ*, and *Brucella suis* and *abortus*. The antibiotic has been obtained as a yellow crystalline hydrochloride which deteriorates rapidly in alkaline solution at room temperature. The "acute toxicity" of aureomycin when injected subcutaneously into mice is between 3000 and 4000 mg. per kg.; daily doses of 60 mg. per kg. by mouth and of 3 mg. per kg. parenterally are well tolerated in man. It is excreted in large quantities in the urine but does not penetrate the blood-brain barrier.

Aureomycin is as effective as penicillin in protecting mice against *Strep. pneumoniæ* type I but is inferior to penicillin against β-hæmolytic streptococcal infections. Clinical trials have been carried out by Prof. Perrin H. Long and his colleagues[8] at Johns Hopkins Hospital, Baltimore. The dosage given by mouth varied from 10 to 60 mg. per kg. of body-weight per day, in divided doses. Intramuscularly a total daily dosage of 3 mg. per kg., given six-hourly, was well tolerated, though there were signs of moderate irritation at the site of injection. Five patients with Rocky Mountain spotted fever seemed to respond to aureomycin in twelve to seventy-two hours, and a patient with chronic brucellosis had a negative blood-culture forty-eight hours after the start of treatment and remained afebrile and asymptomatic for the next two months. The antibiotic sterilised the urine of two patients with a paracolon infection. These numbers are very small and need extending f critical appraisal. There is no question of aureomyc being another penicillin, but if the claims made for are confirmed it should prove useful, particularly f the control of brucellosis and urinary-tract infections.

HOSPITAL ADMISSIONS IN THE NEW SERVICE

SOME idea of the effects of nationalisation on hospit admissions in London can be gained from the experien of the Emergency Bed Service, which is still worked the King's Fund though now on behalf of the fo Metropolitan regional boards. The work of the E.B has been extended by the addition of fever-hospit admissions, responsibility for which was taken ov from the L.C.C. on July 5. These, however, do n account for the 400% rise in the number of calls receiv The rise has been mainly due to a great increase in acu cases. There have been many applications for t admission of chronic cases, though not the deluge th might have occurred: doctors evidently realised that new service could not produce beds overnight. T total number of calls received in the first three mont of the service was 10,974 (acute 8132; fevers 284 and some 500 chronic cases were passed through service to the hospital management committees' waiti lists.

The use of the E.B.S. by doctors is *optional*—th are in no way barred from arranging admissions dir with the hospitals—so this sudden increase is not ea to explain. One possible explanation, and a disturbing o is that doctors are finding it more difficult to patients into hospital and so are calling on the E.B for help in a larger proportion of cases. This vi is supported by the difficulty which the E.B.S. is its experiencing in placing patients. All the fever ca have been admitted and virtually all the acute cas in spite of a quarter of them being over 60 years of a The fever admissions have been fairly simple, requir an average of only 1·5 calls per case. On the ot hand, for every acute case admitted an average o hospitals had to be asked, as against 2·7 for corresponding period last year and 1·6 in 1939. T figure was reached in the healthy month of Septemb and the E.B.S. has so far borne the strain, albeit wi more delays than heretofore; but the winter mont will evidently tax its resources to the utmost. Mea while steps are being taken to establish branch admissi offices outside Greater London. As far as possible th will be run by the existing staff of the hospital mana ment committees, who are being given a short cou at the E.B.S. office in London. The intention is establish centres throughout the Metropolitan regio so that doctors can be sure of obtaining a bed for th patient if there is a vacancy anywhere in his region.

HOUSE COMMITTEES

THE position of house committees was one of t subjects considered on Oct. 6 when the Minister Health met chairmen of boards of governors, regional boards, and of hospital management committe Among the points made were some that have late been raised in these columns,[1] such as the recru ment of management committees from members of t house committees who have shown their worth, and t need for heads of departments to be given their rightf position of responsibility. We understand that it was al suggested that house committees would gain a wid outlook if some of their members actively participate in the work of the management committees. No dou arrangements will vary with circumstances, and the may be places where, instead of appointing a hous committee, it would suffice to appoint house visitor who would keep the management committee in clos touch with its several hospitals.

[8] Bryer, M. S., Schoenbach, E. B., Chandler, C. A., Bliss, E. A., Long, P. H. *J. Amer. med. Ass.* 1948, 138, 117.

[1] *Lancet*, 1948, i. 643; Oct. 2, p. 535

Very extensive data are available on the average heights and weights of school-children in the three zones during the post-war period. In the U.S. zone 1,850,000 school-children were measured in March, 1948, and comparable data are available from December, 1946, and January, 1948. In the British zone monthly measurements of over 10,000 children have been carried out since December, 1946. In the French zone heights and weights of about 370,000 children have been recorded quarterly. These data show some apparent general improvement in both average height and weight over the past year among children in the British and French zones, and some slight improvement in weight, without much change in height, in the U.S. zone. Children in the U.S. zone are, on average, somewhat taller and heavier than in the British zone, possibly owing to hereditary differences.

It is much to be hoped that this large accumulation of data will ultimately be analysed by some competent authority and published with proper interpretations. For the present, however, it seems dangerous to attempt any interpretation without careful analysis, particularly to attempt any *comparison with* various standard "norms" for heights and weights at different ages. It would be necessary to take into account the age at which German children should normally reach puberty, with its pronounced effect on the pattern of growth. Moreover, it is no simple matter to decide what the present average stature of an adequately nourished German child should be at any particular age, bearing in mind the general tendency of Europeans to grow with increasing rapidity during the present century. Rather than attempt any immediate conclusions from these anthropometric data, it seems wiser to rely on the clinical appearance of the children as they are there to be seen.

CLINICAL OBSERVATIONS

About 1600 children in the three zones were personally examined by me in October, 1947, and about 1500 in May, 1948. The towns visited, the approximate number of children examined, and the kind of institutions in which they were seen were as follows:

October, 1947

British zone: Hamburg, Hanover, Essen, Düsseldorf. [illegible] children in 3 schools, a kindergarten, a factory (apprentices), and a nutrition-survey clinic.

U.S. zone: Stuttgart, Nuremberg, Frankfurt. 400 children in 5 schools and a nutrition-survey clinic.

French zone: Trier, Ludwigshafen, Freiburg. 800 children in 6 schools, an orphanage, a gymnasium, and 3 factories (apprentices).

May, 1948

U.S. zone: Wiesbaden, Kastel, Aschaffenburg, Mannheim, Heidelberg. 700 children in 4 schools, 2 kindergartens, a hospital, and 2 nutrition-survey clinics.

British zone: Bonn, Duisburg, Haagen, Dortmund, Düsseldorf. 600 children in 4 schools, 2 kindergartens, 2 orphanages, and a hospital.

French zone: Mainz. 200 children in a school and an orphanage.

This clinical study was deliberately limited to the larger towns, most of which are partly destroyed, because the available evidence goes to show that the serious nutritional problems are practically confined to such towns. Information on food-supplies, vital statistics, the opinion of military-government officers and of German public-health officials, and personal observation during many journeys through the country make it virtually certain that there are no nutritional problems among the "self-suppliers" and "part-self-suppliers" who live in the country and comprise about a quarter of the present population of the British-U.S. zones.

It is reasonably certain that the children here described include a good proportion of those in the worst condition to be found in each of the three zones. In many instances the children for examination were selected by German officials. Inquiry was often made into the basis of this selection, and, on the whole, satisfactory assurances were obtained that a representative sample of children was seen in each locality.

Evidence of Underfeeding (Caloric Deficiency)

Most of the school-children present the appearance of normal health and, undressed, seem in fairly good condition though occasionally hollow-eyed or a little thin, and sometimes with protuberant abdomen, stooped shoulders, and prominent shoulder blades. The girls generally appear in better condition than the boys, and children aged 12–14 better than those 6–8 years. The best-nourished fall into the category of averagely nourished children.

In the British zone, where school meals have been in operation for two years, the distinct impression was gained that the general average of nutrition was more uniform than in the U.S. zone. In the French zone the difference between the best and worst children seemed more pronounced than in the other two zones.

Though the physical appearance of the majority was fairly satisfactory in every school visited, a minority, amounting generally to about 10% but in one school (Kostheim, U.S. zone) involving about a third of the children, were clearly undernourished. The common appearance of these children was that of being undersized, listless, flabby, pot-bellied, and pale. Direct questioning of children presenting this appearance almost always showed that they came from one of the following "vulnerable groups":

(1) Refugees.
(2) Families where the father was absent or dead.
(3) Families who had lost their possessions by bombing.
(4) Large families.
(5) Families with sick parents.
(6) "Problem" families in the social-work sense.

Most of these receive few of the indirect benefits enjoyed by children of established industrial workers, who receive extra workers' rations and part payment in factory products. The condition of children from these vulnerable groups is not revealed in the general statistics, by reason of the better condition of the great majority of school-children.

Pre-school children mostly appeared adequately nourished, only a few being unduly thin.

Adolescents aged 14–18, as seen in secondary schools, were generally in better condition than younger children, probably at least partly for the reason that they came from families in better economic circumstances. In industrial schools, on the other hand, where the lower-income groups were mostly found, there was considerable variation in height, weight, and general condition, and in this group individual cases of definite chronic undernutrition were evident.

Psychological Effects of Underfeeding

Personal impressions were heard from doctors, teachers, and military-government officials about the present psychological reactions of school-children. A common opinion was that, though initial attention in schools was good, children seemed to have difficulty in memorising facts. Many seemed unable to stay awake or to pay attention for the whole period. Emotional instability, especially among older children, was mentioned more than once. Such troubles were said to have notably diminished since school feeding has been established. It is difficult to evaluate these impressions objectively, but nevertheless they are an indication of psychological damage resulting from many adverse environmental factors, including underfeeding.

Deficiencies of Specific Nutrients

Vitamin D.—There is a significant incidence of rickets among infants in the cities. Possibly 1 in every

Relief by Voluntary Agencies.—In May, 1948, voluntary agencies were feeding about 220,000 children, mainly under school age, in the British-U.S. zones. In most cases, however, such supplements have been distributed for a few weeks at most to a given group of children and then diverted to another group, to "spread" a limited number of rations as widely as possible. In a similar manner about 10,000 children in the French zone were receiving in rotation a small number of rations that probably did not exceed 3000 rations on any one day. In addition a considerable number of parcels sent by private persons abroad have been coming into Germany. It is impossible to obtain an over-all estimate of their numbers and the amount of food they contain.

Extra Rations for the Ill and Underweight.—The rationing system in all three zones provides for supplementary rations on medical certification to sick patients and those more than 20% underweight. In the British-U.S. zones the "underweight" ration is for 645 calories daily. The number of persons receiving such supplements varies very much from one locality to another, depending probably on the readiness of local doctors to grant certificates. In the Ruhr district, for instance, the number of the population receiving these supplements is 10% in some towns and over 20% in others where health conditions are apparently no different. These extra rations probably go more often to adults than to children. Direct personal inquiry in various schools generally revealed that the few children who were receiving the "underweight" ration were obviously in need of it. Very often there were others who also appeared in need of extra feeding but had not been certified for it.

Unrationed Food.—In the small towns and villages allotments and gardens are unquestionably of considerable assistance, particularly in the summer and autumn; but in the large bombed cities the number of privately cultivated plots is so few that it is doubtful whether they make any significant difference to the total food-supplies of the people in these cities.

Black Market.—The real extent of the black market is a favourite subject for speculation. It is obviously operated erratically and most unevenly through the population. There is certainly a small group of shrewd and successful traders in black-market food and still a few people with non-essential household property to barter, but most of the working population have no such advantages.

Certain factories have been paying their workers partly in kind, anything from clocks to slide-rules, but it takes time and trouble to trade these for food. More usually the trading is a simple exchange of labour for food. The five-day working week allows the worker to spend one day a week in the country working for a farmer for the price of a good meal and perhaps a few pounds of potatoes and vegetables; but in the neighbourhood of the large cities the price of such labour is cheap and the reward correspondingly small.

For these reasons any estimate of the average number of calories received from black-market sources per head of the urban population must be interpreted cautiously. It is liable to give an erroneous impression of a smooth and efficient distribution, benefiting all classes equally.

German authorities quote a figure between 200 and 300 calories as the average per-caput daily consumption of black-market food. Comparison between the official rations and the actual state of nutritional health of the people might suggest a figure nearer 500 calories, but whatever the true figure it probably declined in the first half of the year with the exhaustion of illegal holdings of potatoes. As one German professor put it, the only generalisation that one can make about the black market is that the most dishonest fare best.

Share in Parents' Rations.—Everywhere in Germany one hears the story that parents, especially mothers, give part of their rations to the children. Since workers and heavy workers receive substantial additions to the basic adult ration, their children particularly are likely to benefit. This frustrates the purpose for which the extra rations are granted —to increase industrial production.

The official rations do not provide sufficient calories for children, except those under the age of 3 years. Every child must therefore receive some additional food from one or more of the sources mentioned above. The diversity of these sources makes it impossible to estimate accurately the average food intake of German children either in terms of calories or of specific nutrients. The best clue to their state of nutrition must come fro the medical evidence.

RELEVANT VITAL STATISTICS

Infant Mortality

Official notifications of infantile deaths in the thi western zones have been as follows:

		Deaths in the first y per 1000 live birth
1938	All Germany (1937 boundaries)	59·8
1946	U.S. zone	95·1
	British zone	107·0
	French zone	88·8
1947	U.S. zone	84·8
	British zone	81·0
	French zone	89·0

Though the general tendency, at least in the U.S. a British zones, is towards a reduction in infantile m-tality, the rates are still more than a third above pre- levels. This is mainly because of the continued h mortality in some of the large bombed cities; instance, in Mannheim and Ulm (U.S. zone) and in so of the Ruhr towns (British zone) rates of over 100 w recorded for 1947.

Tuberculosis

No separate figures are available to indicate the i dence of tuberculosis among children, but the statist covering all age-groups may be taken as an index the general trend. The mortality from all forms tuberculosis has been as follows:

		Deaths per 100,00 population
1938	All Germany	62
1946	U.S. zone	57
	British zone	63
	French zone	65
1947	U.S. zone	55
	British zone	64
	French zone	65

In contrast to the mortality figures, the notifications new cases are considerably above the pre-war figures a continue to rise. However, as explained elsewher there is reason to think that this is largely a pa increase.

Several professors of pædiatrics, with whom conven tions were held, thought that they were seeing rat more cases of tuberculosis in their hospital practices th formerly. It is therefore possible that there is so increase in new cases of tuberculosis among childr though not to the extent that recent tubercul notifications seem to indicate.

German public-health officers often emphasise th adult forms of tuberculosis are now commonly se among children, but it is difficult to find any defin factual basis for this contention.

Other Infections

The incidence of other notifiable infectious diseases not remarkable and is similar to what might be expect in any European industrialised community. One no notifiable condition that now seems to be particular common among children in some urban areas is infest tion by worms, chiefly oxyuris, but ascaris also is sa to be prevalent.

ANTHROPOMETRIC DATA

Any important incidence of underfeeding (simp calorie deficiency) would be expected to lead to retarde growth, which should be reflected in the statistics fo heights and weights of children.

---

1. Tuberculosis in the British Zone of Germany, with a Section o Berlin. Report of an Inquiry made in September-October 1947. H.M. Stationery Office. 1948.

seems to have been made in the supply of city s. Often the only notable building activity is re-roofing of a church or the repair of an ancient ment.

.—Domestic fuel has been short everywhere since woodwork torn from bombed buildings was used up. nter the poor have had to make the most of their fuel by heating one room, crowding into it, and not lating it lest the heat escape.

hing.—German children still living in their own es were comparatively very well clothed at the end e war. At least a fourth of the population, however, bombed out at least once and lost much of their ing. In addition, a sixth of the present population British-U.S. zones came in as refugees, usually with the possessions they could carry. As a result nearly of the population are in definite need of clothing. the rest are rapidly running out of shoe-leather garments made of cotton. A small but important r has been the extreme shortage of sewing-thread, commands fantastic prices in the black market.

p.—The current soap ration provides every person month with a tablet of soap about a fourth the size ordinary cake of toilet soap, just enough to wash ld all over with soap once a week. Some families extra soap in parcels from abroad or as part of the r's wages if he works in the right factory. In addi- , a small amount of detergents is available for the ing of clothes. Few homes can provide any hot r for washing. In the circumstances, especially in midst of all the dust and dirt that surround everyone bombed city, it is amazing to see how clean the ren are kept. Relatively few city children are dirty, pt for their bare feet.

d.—Whatever may be said about the nutritive value present diet, it is certainly extremely monotonous. average German child is fairly happy with a diet of and potatoes, provided there is some fat and a meat to go with it. But the perpetual bread and aked vegetables of the present diet, even though to the healthy child, are certainly not stimulating child with a fickle appetite.

life has been generally disorganised. At least people in the cities in Western Germany have move from their normal homes, either because of ing or because they are refugees. They are living relations or have strangers billeted on them. dreds of thousands are still living in the basements their wrecked homes. Since work must be found ever factories are standing, the breadwinners are forced to live away from home. As in many other tries, families were split up during the war, and the s of separation have been prolonged for the German es in which the fathers have been held as prisoners- ar. An astonishing number of children still say that fathers "have not come home from the war."

Black Market.—Most of the children are exposed every to constant discussions within the family about how rrow's inadequate rations can be increased through lack market. Every member of the family must do t is necessary, and it is said that many well-brought- children have been stealing food to help their families.

Schools.—Almost all the school buildings are dirty, damp, and often partly destroyed. Two or even separate schools use the same class-rooms, working shifts so that school hours are shorter than normal. er, books, and writing materials are still extremely rce. The teachers are shabby and underpaid; they tired and are often dispirited. Too many of them elderly. One gathers the impression that, to maintain ipline in large classes (which sometimes contain up 75 pupils), they rely too much on the system of stern ders and immediate obedience—the system under ich they themselves grew up. Though much effort has been expended by the occupying authorities to revive in the universities true scholarship, which the Nazis suppressed, this is necessarily a long-term project from which, as yet, the city children show little signs of benefiting.

Isolation.—The older children especially seem to share with their parents the feeling of isolation from the outside world and indifference to events taking place in it. Distribution of newsprint is limited, wireless sets are often worn out, and there are almost no posters except those chalked on walls by political propagandists. The former intellectual isolation of Germany, so well described by Thomas Mann,[2] is doubly intensified now and, for the moment, the people seem emotionally exhausted.

DISCUSSION

Life in the bombed German cities has been both physically disagreeable and psychologically disheartening during the past three years. The reaction of the people to their consequent misery has been to focus their complaints on the one thing that they see clearly—the obvious inadequacy of the official rations. Perhaps partly because of this constant insistence on food, a tremendous effort has been made by the occupying authorities to keep the people fed by means of imports; in fact, about two-thirds of the bread distributed in Western Germany during the past two years has been made from imported grain. As a result, the children have been saved from starvation and even from serious underfeeding and malnutrition. But no similar effort has been concentrated on the other influences that make life in the bombed cities miserable: gross overcrowding, lack of warmth, worn-out clothing, lack of washing facilities, disrupted home life, the immoral pressure of the black market, and, perhaps most important for the future, the lack of proper education.

The overwhelming impression of a physician visiting Germany is the dangerous social and psychological environment in which the children of the bombed cities are growing up. By comparison with this, their nutritional health is now a minor issue.

SUMMARY

A brief account is given of the child population of Western Germany and the sources of its food.

The relevant vital statistics are considered.

Observations are presented based on the personal examination of over 3000 children seen on two recent visits to Germany.

It is concluded that, though the general level of health and nutrition among the great majority of children in bombed cities is relatively satisfactory, there is a minority, comprising the "vulnerable groups," whose physical condition is poor.

It is emphasised that, by comparison with their nutritional health, the social and psychological condition of the children is likely to be a much more serious issue.

Grateful acknowledgment is made to the numerous officials of the occupying governments, German public-health officials, doctors, teachers, parents, and children who supplied the information that provides the background of this paper.

In particular I wish to thank the following senior officers for their very great assistance on both visits to Germany: Colonel Milford T. Kubin, public-health branch, O.M.G. (U.S.), Brigadier W. Strelley Martin, M.C., chief, public-health branch, C.C.G. (British), and Médecin Général G. Coulon, directeur de la santé publique, G.M. de la zone Française.

I also wish to thank my colleagues on the UNICEF Mission: Mr. S. M. Keeny, recently chief of the UNRRA Mission to Italy, and Dr. C. E. Raiha, deputy chief, University Pædiatric Clinic, Helsinki, Finland. I have drawn freely on their ideas and observations, but they do not necessarily agree with the interpretations given in this paper.

---

[2] Mann, T. *Yale Rev.* 1946, 35, 223.

10 infants on average would show three or more of the clinical signs of rickets. In some places the incidence is certainly higher; for instance, in Mannheim (U.S. zone) the infants of a random sample of the population, seen by me, were in particularly poor condition; almost all had rickets, and some were marasmic. This city has an unusually high infant mortality, which is probably due to two causes: the disorganisation of its milk-supply, and the large number of families still living in the basements of wrecked houses. Synthetic vitamin D ('Vigantol') is manufactured in Germany, but its distribution for the prevention of rickets is not always satisfactory.

Vitamin A.—There is a theoretical possibility that vitamin-A deficiency might arise through a lack of sufficient fat in the diet to facilitate the absorption of carotene. However, there appears to be no objective evidence of such deficiency among the children. Slight degrees of follicular hyperkeratosis are fairly frequent, as in British children, but it is reasonably certain that vitamin-A deficiency is not the only cause of this condition. No complaints were made of poor night-vision (hemeralopia) among children.

Vitamin-B Complex.—There is no clinical evidence of deficiency of any component of the vitamin-B complex, except possibly riboflavine. This is scarcely surprising in view of the good amounts of the complex that must be provided by the high-extraction cereals now commonly consumed. An occasional case of very mild angular stomatitis may be encountered, doubtfully due to riboflavine deficiency.

Vitamin C.—Among the children examined in October, 1947, the incidence of gingivitis was rare. A quite different impression was gained in May, 1948; in some localities inflamed gums seemed to be unusually common among the children; further, out of 1500 children seen 3 cases were discovered in which the gums present the swollen livid hæmorrhagic appearance of clinical scurvy. In several other cases the gums were unusually swollen though no longer acutely inflamed, suggesting partial healing of scorbutic changes. By May, 1948, when the second survey was made, some green vegetables had already been distributed in most localities. The impression was gained that, had the survey been conducted a month earlier, more scorbutic gingivitis would have been seen.

Fruit and green vegetables were extremely scarce in the large cities during the past winter; moreover, the partial failure of last year's potato crop was a further limitation to the supply of vitamin C. It is difficult to avoid the conclusion that there has been a significant incidence of vitamin-C deficiency among children during the spring of this year.

Protein.—Famine œdema has been a popular clinical diagnosis in Germany during the post-war period, as is usually the case in a country short of food and under military occupation. However, in the course of four tours carried out by me in the past three years, and covering 25 large towns in western Germany, not a single case of undoubted famine œdema, due primarily to lack of food-supplies, has been seen either among children or adults; this despite the fact that the German public-health authorities were often responsible for selecting the subjects examined and had opportunities to produce their cases, if any existed. The last undoubted cases of famine œdema seen by me were at Belsen concentration camp.

Serum-protein determinations have been carried out among samples of the child population in the British and U.S. zones in recent months. It is to be hoped that the results of these surveys will ultimately be published. Without wishing to anticipate their publication, I may say that the results give no grounds for anxiety.

The present extreme shortage of animal protein in the common diet tends to be emphasised by the German public-health authorities as a matter of physiologi importance. But there is good reason to think that t mixture of amino-acids from various vegetable sourc together with the amount of milk regularly provided the ration, are sufficient at least to prevent any seri protein deficiency among children. There can be question, however, that the present supply of milk a other sources of animal protein generally falls far sh of a level that could be considered ideal and, moreov is much below the level to which the Germans h been accustomed.

Fats.—Fat is valuable as an article of diet beca it is a concentrated source of calories and has a h satiety value. Moreover it is extremely useful for cook and for making the diet appetising. Nevertheless th is no good reason for believing that lack of fats is lead to any serious physical damage to children in German

Iron and Calcium.—The results of hæmoglobin det minations carried out on children in the British and U zones were kindly made available for inspection by British and American public-health authorities. Fr the figures submitted I am satisfied that there is important incidence of disabling anæmia among children. Individual cases of pallor suggesting anæ were encountered in the course of examining childr and it is concluded that there is probably a small incide of moderate anæmia, probably due to iron deficien among the city children.

There is no simple clinical way of deciding whether l of calcium is a limiting factor to the growth and devel ment of German children. Milk, the most import dietary source, is provided in good amounts for youngest children, but for the adolescents, especia supplies are seriously below desirable levels. In British zone the supply of calcium is improved by addition of calcium carbonate to the bread, as the practice in Great Britain.

Iodine.—Simple goitre is common among the child in the southern part of the French zone and some p of the American zone. These have always been cent of endemic goitre. There appears to be no defin evidence whether the incidence has altered as a re of the post-war food restrictions. Lack of iodine probably the primary cause, though other factors, as the consumption of certain vegetables, may pl some part.

Dry Skin.—Several cases of unusually dry d quamating skin were observed in almost every group children examined. The incidence appeared to be hig than could be considered normal. However, there is certainty that this can be considered a sign of nutritio deficiency; lack of soap may be an important cont butory factor. In view of this lack it is remarkable h clean and healthy the skin appears in the great majori of children.

ENVIRONMENT AND MENTAL HEALTH

Though the state of physical health and nutrition the great majority of city children is thus relative satisfactory, one cannot feel the same about their ment health. Their daily life is passed in an environment th presents many bad sociological and psychologic influences, tending to encourage insecurity and frustr tion, with the danger of consequent aggressi compensations.

Overcrowding.—Most of the large cities in wester Germany are 20–80% destroyed. Something of th vastness of the problem may be gathered from th calculations of a Hamburg architect that there are, i the whole of Germany, more than 520,000,000 tons o rubble still to be cleared. Probably 1 room in 4 has bee destroyed. In addition, from the influx of refuge Germans 1 person has been added to each 4 who must b housed. Nevertheless, except for the miners, no significant der to be the dictatorial methods being adopted the higher level of bureaucrats both in the research the administrative sphere. They are delighted to visitors from the United Kingdom. No-one is r than they that research work should be expanded, they cannot understand why their opinions are so ily ignored—or at least so it appears to them.

hat is even more disturbing is the suggestion that ng man can start doing sound research the moment rives in a colony. This is fundamentally wrong, t in the case of the basic sciences such as chemistry physics. And Africa is not the place for such basic to be done. The United Kingdom, with its well- pped research institutes, whether university, govern- , or industrial, is the place for such fundamental to be carried out. It is only as the stage of field whether laboratory or clinical, is approached that omes incumbent for the work to be done on the What does not appear to be appreciated in certain rch circles in Great Britain is that no reliable on medical (and nutritional) problems can be d out until the persons undertaking it have a knowledge of the people on whom it is being done of their conditions of life.

ination of Colonial Medical Service and Colonial al Research Service

e second danger is the lack of coördination between Colonial Medical Service (C.M.S.) and the new ial Medical Research Service (C.M.R.S.). In these of the glorification (some would say almost the ation) of research, there is a very real danger of e most promising and outstanding of recruits for C.M.S. being recruited for the C.M.R.S. and, in due e, receiving all the plums of the service in the way ccelerated promotion and the better-paid appoint- The effect of this policy on the C.M.S. would be ous. Any able young doctor proposing to work colonies would immediately go for the C.M.R.S. of the better prospects, thus leaving only the ones for the C.M.S.

is required is that, except in special cases, ment in the first instance should be primarily to M.S. After a preliminary period of, say, two years, r to the C.M.R.S. should be considered if the has shown any special aptitude for research. transfer should never be automatically permanent, ample opportunity should be allowed for interchange een the two services. Conditions of service should e same in both, and there should be equal oppor- ties for promotion to the highest levels. In this the standards of both services would be raised, there would be no opportunity of the health services the colony suffering because of the brains all being ntrated on the research side. After all, a sense oportion must be maintained, and research-workers never forget that, so far as medicine is concerned, rch is the handmaiden of the practising doctor.

SOME PRACTICAL SUGGESTIONS

e critic should always try to be constructive lest be dismissed as being merely destructive. Let me mpt a bare outline of how the Colonial Medical vices should develop.

Conditions of service must be improved immediately; , in view of the developments in this country under National Health Service Act, the salaries to be d under the new scheme must be taken as the basis salaries in the colonies. Unless the financial attrac- s of the colonial services are as great as those in at Britain, the right type of man will never be ained. A scheme must be evolved whereby there l be full interchange between the higher ranks in clinical side in the colonies and in the United Kingdom. For instance, those of registrar status in the United Kingdom should be encouraged to accept positions as consultants in the colonial service for a period, on the strict understanding that by so doing they will lose neither in seniority nor in superannuation rights, should they ultimately decide to return to service in Great Britain. Similarly, promising men of consultant status in the colonies should be encouraged to spend periods of, say, two or three years working in this country, again with no loss of seniority or superannuation rights. This was a point which was emphasised, particularly in connexion with the new medical schools in the African colonies, by the late Professor McSwiney, whose outstanding report on the subject appears to have been permanently lost in one of the many pigeon-holes of the Colonial Office.

On the research side, as already mentioned, the new Colonial Medical Research Service must be closely linked with the Colonial Medical Service. As in the case of the C.M.S., there should be a close association with research-workers in the United Kingdom, both as regards personnel and as regards the work. For instance, it would be a waste of time, money, and man-power to build and equip elaborate research laboratories and institutes in the colonies: the fundamental work in biochemistry, pharmacology, physics, and the like can all be done much better in research institutes in the United Kingdom, provided there is close collaboration with the men in the field—i.e., the workers in the colonies must be consulted about the work to be done, kept in close touch with the progress of the work, and allowed to spend spells in the laboratories in the United Kingdom when necessary. Conversely, the chemists and the laboratory workers in the United Kingdom must visit the colonies at regular intervals so as to be able to appreciate the full implications of the work in which they are participating.

In all these matters the fullest consultation must be maintained with the men in the field. As already pointed out, the present tendency to ignore the men with most practical experience of tropical medicine is not only alienating the members of the Colonial Medical Service but is also tending to the preparation of plans which have little hope of success.

In spite of all that has been said about the necessity for research on such fundamental questions as the incidence of disease and malnutrition, this does not mean that there are no short-term problems to be tackled immediately. Even though we are so ignorant about the nutritional status of the native, there are areas where gross malnutrition undoubtedly exists. Then there are the vital problems of the control of the tsetse fly, the treatment of trypanosomiasis, the use of insecticides such as D.D.T., and the control of helminthiasis. All these can be tackled in a practical manner pari passu with the inauguration of the more elaborate research programmes.

All this will require more men and money, and much more money than the Treasury will concede except under greater compulsion than has so far been exerted. This is not the place to argue the point; but, if it is conceded that the only hope of avoiding world starvation is the full development of tropical Africa, and that this development depends for its success on raising the physical status of the natives and making life there healthier for white men, even the Treasury will find it hard to enforce its conventional obstruction to the necessary expenditure.

But, above all, what is required now is direct access of the C.M.S. and the C.M.R.S. to the Secretary of State. Much lip service has been paid of recent years to the development of the colonies. On the medical side little of practical value has resulted, and it is clear that one reason for this is that the medical services

MEDICAL RESEARCH IN AFRICA

FROM A CORRESPONDENT

Now that it is at last agreed that the only hope of avoiding world starvation lies in the immediate and full development of the food-producing potentialities of tropical Africa, it is evident that medical, veterinary, and agricultural research assumes, to use a popular war-time phrase, "top priority." Officially, this is said to be an accomplished fact, but a recent tour of East, Central, and South Africa raises doubt as to whether the true urgency of the position is appreciated in Whitehall and whether the matter is being tackled in the right manner. The following comments and criticisms apply primarily to the medical aspects.

The urgency has been made abundantly clear by the writings and speeches of such international experts as Sir John Boyd Orr and Sir Jack Drummond. What is not so generally appreciated is the nature and the size of the medical problems involved. If the full food-producing potentialities of tropical Africa are to be realised, it is essential that the physical capacity of the native should be developed to the fullest possible extent. From the medical point of view this involves improving the nutritional status of the native and controlling the diseases to which he is subject—two subjects on which we are still very much in the dark. Through no fault of the members of the Colonial Medical Service, but simply because the men and the money have never been forthcoming, there is still relatively little information about such elementary data as the incidence of disease in different colonies and protectorates. For instance, the full geographical extent of the yellow-fever virus is still unknown. The evidence for the incidence of leprosy in East Africa is entirely inadequate and the first systematic survey of the extent of this disease in East Africa is only now being carried out. Again, there have never been any facilities for carrying out controlled clinical trials of new therapeutic agents there. Anyone with even a superficial knowledge of tropical medical literature must have been impressed with the number of published articles based upon the clinical trial of a new preparation in only 50–100 cases, though thousands (if not hundreds of thousands) might have been investigated if only the Colonial Office had made it possible. Closely interrelated with this question is that of the varying reaction of a disease to a given drug in different parts of the world—even in different parts of the same continent. Kala-azar is a case in point, as are the contradictory reports now being received about the efficacy of 'Paludrine.'

As regards the nutritional status of the native, scientific data are again lacking. Surveys have been made but with one or two notable and oft-quoted exceptions they have merely touched the fringe of the problem. Even those which have been made are partially invalidated by the unfortunate fact that we are still hopelessly ignorant of the physiology and the feeding habits of the normal native. The result has been that socially minded publicists have been making statements about the nutritional status of the native for which there is no scientific basis. For instance, what scientific reason have we for declaring, as is sometimes done (and regrettably, let it be added, by some who have allowed political bias to impinge upon scientific reasoning), that the nutritional requirements of the African native are the same as those of Europeans? Or, to take a more specific instance, assuming for the moment (and it is only an assumption) that the calorific requirements of, say, an 80-kg. native doing a given piece of work are the same as those of an 80-kg. white man, what evidence is there that the native requires the same proportion of carbohydrate, fat, protein, and vitamins as the white man?

THREE MAJOR RESEARCH PROBLEMS

To indicate the problems involved, even in bare outline, is sufficient to emphasise their tremen scope, and it is clear that fundamentally there three major research problems which, though cl interlinked, must be considered separately to a making confusion worse confounded.

First, we must acquire more data on the no physiology of the native and his nutritional st What are his "normal" height and weight? Ar pulse-rate and blood-pressure the same as thos Europeans? Are there any differences between metabolic processes and those of a white man? is his normal reaction to physical exertion and to emot stress and strain? What is his physical stam What are his normal requirements of sleep? Unt have at least some elementary data on such matters, it is impossible to evolve any long-term p for his betterment.

Secondly, surveys must be made on the inciden disease in different areas. How widespread is tub losis, and what form does it tend to take in the nat How widespread is schistosomiasis? What is the incidence of relapsing fever, and what are the relationships between the louse-borne and the tick-l varieties? Closely linked with this subject is th vital statistics. What is the expectation of life i native? What are the infant and maternal mort rates—not in areas covered by hospitals and clinic in the whole colony concerned?

Finally, there is the problem that the mere me of tropical medical research usually suggests—the n of treating such classical diseases as leprosy, ma schistosomiasis, and trypanosomiasis. Here much been accomplished, but much more requires to be particularly in ensuring that trials of new remedie carried out on a sufficiently large scale and with en controls to make the results capable of stati analysis.

TWO DANGERS

Two unfortunate tendencies are appearing in plans to cope with research. It is probably true to that the Colonial Office has accepted the prin that medical research in the colonies is a matte some urgency; but unfortunately, as all too man us are learning from bitter personal experience, time-lag in governmental quarters between accept and action is liable to be all too long. What is n more disturbing, however, is the evidence that action that is being taken is along the wrong lines.

Remote Control from Whitehall

The first danger is that too much control is b exerted from Whitehall, and that insufficient atten is being given to the views of those with years of experi in the colonies. Fundamentally, the approach to rese is the same the world (and science) over, and no would dream of questioning the advisability of obtai advice from experienced research-workers and adn strators in chemistry, bacteriology, nutrition, phar cology, and medicine. But advice is a very diffe matter from direction, and you cannot direct rese in Africa from an office in Whitehall or an armchai the Athenæum. Neither can you send a bright yo research-worker from this country out to Africa expect him to do good work until he has had ac experience of the conditions under which he has to w

Quite frankly, and for the sake of Africa frank is now essential, the workers in the field are becom tired of the continual stream of "experts" being flo out to them for brief tours by the Colonial Of without any definite action being taken as a result their reports. They are resenting even more what th

In England Now

ing Commentary by Peripatetic Correspondents

TY years. I suppose, is a long life for a dining , but our members were very carefully chosen a dozen men who had been close friends all through student years picked the rest. So, though what was a hilarious evening for a bunch of lively young idents has become a more sober gathering of senior with a sprinkling of specialists and oddments, come; and I think the club will survive until all dead, bedridden, or too broke to afford the p.

of the members has died yet: 3 (out of 15) had phthisis and 1 has a colostomy, but they are mbulant: nor do any look potentially broke— of us look thin and ill, and most of us look worried. outsider would guess we were a pretty successful perous lot of doctors. My own first impression year, on seeing them gathered round the cocktail waiting for the gun, is that they have not changed ot in face, or facial expression, or tone of voice. versational gambit: only in hair, for all but 2 are going grey and 1 is getting a little bald. But said outsider was given a flash-back of the club it was founded he would soon spot the effects of years' battering by night-calls, overdrafts, and strations inseparable from family life.

h the same applies to our conversation. Though t one another in the same words we no longer ak at once; we listen, if not gravely (that will in the next twenty years) at least with restraint, at the other has to say. We were always indi- sts, but where once our opinions were second-hand every member knew whom they came from), now are based on first-hand experience plus personal ce, and are therefore almost unshakable— t of twenty years' laying down the law.

of us have boys and girls at school, so there was ual parental false modesty over the children's : "Peter hasn't a hope of getting through Entrance . . . ."; "Jimmie has been two years thelred's and is still bottom of the second form that sort of thing, with an occasional casually remark that Peter or Jimmie won the open yards at the age of 12, or topped the batting at his prep. school, but what's the use of that? ishingly high proportion of us have faced near- in our wives or children; but of that we did not We don't go in for speeches, thank God, but there the usual reminiscences, starting with a "Do you ber . . . ?" to one's neighbour and taken up by after the other across the table. There was that mas when our minstrel troop performed at a home aged sick. The troop arrived to find the inmates round long tables in the big hall, apparently g for our show to start. But half way through the chorus it suddenly became clear what they were —TEA. From the moment when the bread and clattered in the audience never looked our way and such was the clash of knife and teaspoon that oisy show was audible only on the stage, if that. when our president, slightly tight, came on to ince "the next item is a song by Mr. Robinson," re-entered to say "Mr. Robinson will now sing Blue Room," and finally came on a third time and into song the inmates didn't smile. If our outsider peped in while this little story was being pieced her he would have realised that the changes in us 1928 have been merely organic rather than ional.

* * *

e eminent surgeon on my right looked askance at roken nails and roughened scratchy hands, while the ly eminent physician on my left watched and ered why I fumbled with the armament of cutlery. y hadn't a clue—could not guess that throughout week I had been working at a Volunteer Agricultural p, lifting potatoes and picking apples at 1s. 7d. hour. As I gobbled the roast turkey I reflected that previous evening meal had been of meat which might have functioned in the 1938 Grand National and I washed up my simple platter and tools in the communal tub of greasy water. What would our scarlet coated toastmaster have made of that?

From the literature received one fondly imagined one would be accommodated in an ancestral mansion. Alas B— Hall was a ruin and our lot was cast in huts. But having made my bed with the four blankets and pillow provided, I for one at the end of the day's work was ready enough to lie in it, however hard it was, and however restless and adenoidal my campmate in the lower berth might be.

Reveille was at six: no bugle note, but shouts of "Wakee-wakee" and thumpings on the hut side. After a very adequate breakfast—the porridge especially was good, though lacking sugar and milk—we went by lorry car, or bike to our allotted farm, carrying sandwiches whose size was more remarkable than their succulence. "My" farmer had applied for only two volunteers for apple-picking, and my mate was a silent and aloof miss from Surbiton. The fact that it was her second week in camp perhaps accounted for her superiority. We worked from 8 A.M. till 9.30 when there was a short interval for refreshment. At noon we lunched with the other farm-hands in a shed, the farmer providing copious hot sweet tea to combat incipient shock or collapse. Another three hours and we were free to return to camp, feeling we had well earned the 11s. 1d. that Farmer Giles doled out from a huge wad of notes. Personally I don't think he'd made a bad bargain.

There was a certain fascination in apple-picking—the skilful laying of the ladder to ensure the maximum gathering, the delicate touch to prevent one of a great clutch falling, the satisfaction of lifting three at a time in each hand. Some of the fruit, mostly "Lane's," was magnificent, often scaling well over a pound apiece: and a reddening apple with the dew still on it is a far prettier sight than, shall we say, a gangrenous appendix.

The same cannot be said of spud-lifting, where one is the slave of the inexorable spinner and must follow up one's stint ventre-à-terre, keeping pace with the regulars and locals who are paid considerably more for a day's work, so that one has verily to bear in mind the Parable of the Vineyard. It's a backaching, soul-destroying job; but preferable, as well I know, to sugarbeet lifting or to threshing, especially of beans.

Should this be read by the village doctor who (out of surgery hours) courteously lifted an apple twig from my palpebral conjunctiva, I should like again to express gratitude. It was odd I thought that neither of the two uniformed members of the B.R.C.S. who graced the camp knew how to evert a lid and had been warned by doctors against the attempt. Surely it is the simplest of measures, resulting in immediate and miraculous relief of considerable agony.

To one in search of recreation as opposed to holiday I would recommend a V.A.C. But he, or she, must be a good "mucker-in" and have sturdy digestive and sleeping habits. My camp was clean and well run: the food and showers were hot and much was done for one's entertainment and convenience. For my part, I shall go again and add my drop to the ocean of production: albeit my earnings for a week, by the very sweat of my brow, were equalled almost to a shilling by the cost of my Hospital Dinner (plus wine).

* * *

After recovering from the preliminary shudder set up by your annotation *Patients' Reading* (Oct. 9), one has to admit there may be something in the idea. The shudder was solely in response to the notion of "prescribing books like medicine, and requiring a report from the librarian on the effect on the patient." Just imagine ploughing through the folder of notes, path. forms, blood-counts, X rays, and the rest, so swiftly collected by the modern medical case, and then stumbling on a note: "Will the Librarian please see? P.A.; R.B.C. now 3,500,000. Is he strong enough for James Joyce?" Before long I suppose students will be asked the volumes to prescribe for specific diseases and the textbooks on therapy will note "*Gone With the Wind* is almost specific in this condition" and "Meredith may be exhibited, but must be instantly withdrawn on signs of the patient's weakening."

A librarian's advice would indeed go far to prevent occasional unfortunate selections, instanced by the have not had the direct access to the Secretary of State that is essential. One way in which this could be accomplished would be by immediately increasing the seniority of the office of medical adviser to the Minister —if necessary, to that of an assistant secretary of State—so that he would have the direct access which is necessary. If this is done, it is equally essential that the occupant of the post should be a doctor of outstanding ability, both medically and administratively. At the present stage much could be said for appointing him from outside the Colonial Medical Service. Men of the calibre of the late Professor McSwiney, with his unusual combination of outstanding ability in the spheres of medicine, research, administration, and medical education, may unfortunately be rare, but it is such a man who is required at the moment to undertake the reorganisation of the Colonial Medical Service and to ensure that his reforms are transmitted personally to the Secretary of State for immediate action.

W.H.O. CONFERENCE ON STREPTOMYCIN

AT the third session of the *Interim Commission of* the World Health Organisation, at Geneva, in April, 1947, it was resolved to set up an expert committee on tuberculosis. In the first report of the committee,[1] accepted by the Interim Commission, the various field activities and techniques for tuberculosis control were set out and it was stated that the best contribution which W.H.O. can make to tuberculosis research would be in developing and recommending uniform procedures. Special problems would require the services of subcommittees who were expert in highly specialised fields. Among the most urgent of these problems was the evaluation of new chemotherapeutic agents such as streptomycin, and accordingly a conference on streptomycin therapy in tuberculosis was convened in New York on July 30 and 31. The following experts attended: Prof. K. Choremis (Greece), Prof. C. Cocchi (Italy), Dr. Robert Cruickshank and Dr. M. Daniels (United Kingdom), Prof. R. Debré (France), Prof. R. Dubois (Belgium), Dr. H. Corwin Hinshaw and Dr. H. McLeod Riggins (U.S.A.), with Dr. H. E. Hilleboe (U.S.A.), a member of the parent committee, as chairman. In addition, American experts in different fields of streptomycin therapy and in the pathology and bacteriology of tuberculosis were invited to attend the meetings.

In the first three sessions the discussions covered the general principles of chemotherapy in tuberculosis, the results obtained with streptomycin in different forms of tuberculous infection, studies in combined chemotherapy, and laboratory methods for the diagnosis of tuberculosis and for the control of streptomycin therapy. A strong impression from the reports of members from some European countries was that acute tuberculosis in childhood (tuberculous meningitis and miliary tuberculosis) was much more common there than it is in the U.S.A., and that results with streptomycin in these acute childhood infections were more encouraging than earlier reports had suggested. The present position in the chemotherapy of pulmonary and surgical tuberculosis in the U.S.A. was reviewed by Dr. J. Barnwell, of the Veteran's Association, who analysed over 3000 treated cases (shortly to be published); by Dr. Hinshaw, representing the Trudeau Society; and by Dr. Riggins, representing the American Tuberculosis Society; while Dr. Floyd Feldman outlined the trials now being sponsored by the U.S. Public Health Service. The tendency in American centres is to reduce dosage to 1 g. per day (or 20 mg. per kg. body-weight), with a resultant reduction in toxic reactions but with little obvious change in therapeutic effect, and to shorten the duration of treatment 42, or even 28 days in cases of pulmonary tuber in the hope of preventing or minimising the develop of streptomycin-resistant strains of the tubercle ba Remarkable results were reported by Dr. Edith Li in the treatment of small groups of cases of tuberc meningitis and miliary tuberculosis with strepto and 'Promizole' (a sulphone compound), the drug being continued for many months after strepto therapy was stopped. Dr. Daniels described the org tion, under the ægis of the Medical Research Co of the streptomycin trials in tuberculous menin miliary tuberculosis, and progressive bilateral pulm tuberculosis in Great Britain. Laboratory me were discussed by Dr. Cruickshank and Mr. W. Stee while Dr. R. J. Dubos made a strong plea for dis "egg-concoctions" in favour of the oleic acid and albumin diagnostic medium for the isolation of tubercle bacillus.[2]

At the final session, attended only by members W.H.O. subcommittee, recommendations were dr concerning the use and value of streptomycin in t culosis. The following points were stressed:

> In most forms of tuberculosis streptomycin is at be adjuvant to other recognised therapies; its use is not d of risk of the development of toxic reactions, and, serious, of streptomycin-resistant tubercle bacilli which be transmitted to exposed contacts.
>
> The drug should at present be distributed through go ment or other responsible health agencies to hospital institutions where it can be used under expert superv Patients with tuberculous meningitis and miliary tuberc in whom the use of the drug can be a life-saving proc should have priority.
>
> In certain other forms of tuberculosis—e.g., acute monary, tracheobronchial, sinuses, and fistulæ—strepto judiciously used, could be a useful adjuvant for therapy.
>
> Size and duration of dosage could not yet be defined narrow limits.
>
> The wide variations in methods of reporting the resul streptomycin treatment from different centres made parisons of the efficacy of different therapies impossible, the committee urged the adoption of certain minim standards of reporting which will render such compar possible and valid.
>
> *W.H.O. should continue to encourage and facilitate* i national study and coöperation in researches on chemotherapy of tuberculosis.

The memorandum embodying these recommendat has now been accepted by the tuberculosis ex committee and forwarded for approval to the execu board of W.H.O.

After the conference, the delegates made a week outing to the Homer Folks Sanatorium, Oneer belonging to the New York State Department of Hea where many clinical and laboratory problems in streptomycin therapy of tuberculosis were discussed detail.

[2] *Amer. Rev. Tuberc.* 1947, 56, 334.

"... sickness used to arise from too little food. Nov comes from too much worry. Doctors could only allevi not cure, the old kind of disease until social conditions w improved. To-day they can only deal with the symptoms the present diseases, because they cannot produce wo stability. Add to this the fact that modern medicine is w on the road to abolishing, or at any rate rendering unimporta many of the more serious illnesses that used so often to fatal, like diphtheria and pneumonia, and you see that or again science is giving us the physical tools of mastery, b they are not much use to us because we remain mental a lot of frightened, irresponsible, and neurotic children."—*New Statesman and Nation*, London Diary, Oct. 9, 194 p. 297.

two mean temperatures (0·76 ± 0·05°F) is highly nt, t being 14·97, and P less than 0·01.

temperature curve obtained by superimposing 22 known ovulatory temperature curves may be rded as characteristic of true ovulation, as proved by onset of pregnancy. The change between the mean ulatory and postovulatory temperature levels red sharply and within a period of twenty-four in the 22 women.

e basal body-temperature curves of a patient under vation for infertility show significant differences in rate of the ovulatory rise of the temperature at mid-intermenstruum. The mean preovulatory temture in 12 consecutive menstrual cycles was 98·29 ± F, and the mean postovulatory temperature 98·91 ± F. The difference (0·62 ± 0·05°F) is highly significant of the same order as observed for fertile women, g 12·60, and P less than 0·01. However, the mean temperature rose gradually rather than abruptly g the five-day interval between the mean pretory and postovulatory temperature phases. A cant rise above the mean preovulatory temperature did not take place until the fifth day after the start e change, compared with one day in normal fertile en.

e patient has no demonstrable pelvic pathology. tubes are patent, and her basal body-temperature and the histological appearance of her endometrium compatible with regular ovulation and corpusformation. She has been under the care of doctors for the investigation and treatment of ility during the past eight years. Numerous nations with seminal fluid containing normal atozoa in quantities between 100 and 250 million ml. have been carried out, without success. It is ceivable that normal active sperm could have to fertilise an ovum at one time or another if ever vum had been available. While the cause of her ility is unknown, it is therefore presumed to be due hanical failure of ovulation. It is also believed that owly rising type of temperature curve which this exhibits may be regarded as an abnormal type e associated with the mechanical failure of

detailed report which is being prepared will additional experimental evidence in support of clusion.

ncisco, California. ALLAN PALMER.

INDEPENDENCE IN RESEARCH

—Sir Henry Tizard's inaugural address as president British Association, and the *Times* leading article pt. 9, both fail to emphasise one most vital factor e progress of scientific research: it is the virtual ssion in this country of the independent thinker the laboratories wherein he used to carry out his ents, and the restriction of facilities for research ch workers as find favour with a small but powerful p of "experts." This narrows the lines of approach thwarts the efforts of the independent thinker who past has supplied nearly all fundamental progress. entirely agree with the *Times* on the importance of biological sciences in the problems of disease in man, ls, and plants. But why then has an independent like the Brown Institution—where this fact was ed and acted on—been suppressed? Probably the infectious diseases in the world are due to one other filter-passing virus, and the most fundamental lem in relation to their control is to be able to grow —apart from other forms of life—according to their iological requirements.

e writer had an extensive research on this problem ped out and in progress when in 1944—with the tion clearly indicated in many experiments— laboratories were destroyed by a bomb. Much of the al apparatus which had been built up was salvaged now lies idle at Camberley. Why—I ask—have laboratories not been rebuilt, or some existing ding acquired wherein the necessary equipment could reassembled and the writer given facilities for coming this vast research, possessing, as it does, an nomic value of many millions of pounds sterling? It was at the Brown Institution that the writer solved the problem of producing a diagnostic vaccine for Johne's disease of cattle, thereby bringing it under control, and later laid the foundation of much modern work on viruses by the discovery of the "bacteriophage." The research on the growth of the virus group as independent forms of life was being equally successful when the writer was deprived of his post and all facilities for continuing this and other researches on hand.

Camberley, Surrey. FREDERICK W. TWORT.

M.R.C.P. EXAMINATION

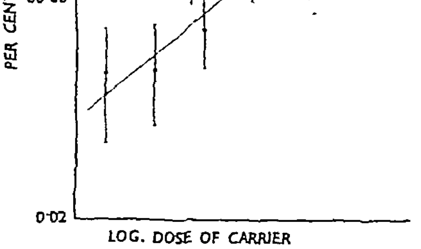
SIR,—Sir Henry Tidy's thought-provoking and illuminating letter of Sept. 25 interests me very much. I have been amazed to find how rapidly two Censors can uncover my points of weakness in the clinical examination lasting eighty minutes: now I am more amazed that a Censor can in fifteen minutes mark a paper which I, who have just written it, cannot read through in that short space of time. This examination sets out to be a test in clinical medicine; the papers are remarkably clinical in their application, and the clinical itself is certainly a test of powers of observation and ability to make up one's mind, and a battering from two very well-informed gentlemen who want to know how well one's mind is made up and will shatter one's opinion if they can.

A man working in hospital outside the select teaching group has no other opportunity to prove and improve his standard. Experience alone teaches. The clinical examination can be an exhilarating event, even for the candidate who fails; for excellent cases are presented in an atmosphere of such tension that detail is long carried in the mind, and I learn as much in the eighty minutes as otherwise I might in perhaps a fortnight. It is therefore well worth while "having a go" though pounds are scarce and the cost of such a visit to London is high.

THRICE TRIED.

ASSESSMENT OF DIPHTHERIA PROPHYLAXIS

SIR,—I have read with interest Dr. Bousfield's article of March 8, 1947 (p. 286) on his clinical trials of Holt's diphtheria prophylactic P.T.A.P. The efficiency of immunising procedures in general, and of diphtheria prophylaxis in particular, can be better evaluated if one utilises certain statistical devices in considering the quantitative relationship between the vaccine potency and the results obtained. In estimating progress in prophylaxis one must take into account the individual differences in reaction; those who are least responsive to immunisation require a relatively very great increase in vaccine potency if inoculation is to be successful.



With regard to diphtheria prophylaxis, an examination of the data given by Hartley[1] for guineapigs shows that when the quantity of toxoid injected was increased from 2·5 Lf to 5 Lf, the Schick-conversion rate rose from 40% to about 85%, but a further increase to 20 Lf only raised the conversion-rate to 93%.

The information supplied by Bousfield revealed a similar phenomenon. He immunised groups of children with 5 Lf of purified diphtheria toxoid adsorbed on to increasing amounts of aluminium phosphate carrier. In this work the increase in Schick-conversion rate sufferer from persistent jaundice who chose on too superficial but sympathetic grounds *Forever Amber*, and the G.P.I. who roared his head off all the way through one of Laski's books on Socialism, no less. Then there is the complication first described by P. G. Wodehouse, the physical weight of the tomes offered for recumbent reading. The patient with epigastric tenderness could hardly be expected to stomach Scott; he should be started on Shelley, progressing through Bacon to the Brontës. Digestion of the first three chapters of *Vanity Fair* indicates complete symptomatic relief.

---

[1] Hartley, P. *Wiss. Woche Frankft a. M.* 1934, 3, 81.

Uncoöperative sufferers on extra fluids will do well on P. C. Wren, or might advantageously have *The Ancient Mariner* recited to them t.d.s. Victims of anorexia nervosa could only thrive on Damon Runyon's *Piece of Pie*, in which a character by the name of Nicely-nicely Jones enjoys an eating competition of toothsomeness more than somewhat. The B.M.R. in thyrotoxicosis can be lowered to normal in a week by *Paradise Lost*, and Gibbon will quieten even acute mania. Anyone with a gastric ulcer should be put to bed with a copy of Lin Yutang's *Importance of Living*, while the essays of Stevenson and Lamb can knock at least 50 mm. Hg off a hypertensive blood-pressure. *Alice in Wonderland*, followed by anything from Chesterton and Belloc, may be reserved for the non-specific restoration to sanity in us all. Pregnancy will pass peacefully with Jane Austen. For general depression how about Leacock, Thurber, Benchley, et al.? For lethargy there is always Peter Cheyney, and insomnia may be instantly relieved by any reputable textbook on hæmatology.

* * *

As usual at this season the winter-pants problem has been causing me concern. Whether to don them as soon as the mornings get chilly and be boiled by midday; or to start work blue and begin to feel about right at lunch-time. This isn't a question on which tradition gives any guidance. Everyone knows that he must ne'er cast a clout till May be out (though there is some disagreement about the capital letter in "May"); but on when to resume the cast clout the wise rhymesters are silent. No-one says:

> Don thy woolly smock
> *As soon as it be Oc.*

Or:

> When chestnut leaf do fall
> Cotton ain't no use at all.

Or even:

> Car won't start in the morning
> Shepherd's warning.

Clearly it was the chills of late spring, rather than of early autumn, that our ancestors feared. Anyway, since it is looked on as eccentric, even at the peculiar club where I feed, to doff one's underwear in the cloak-room, I support that school which stays in bed till noon and carries on to the bitter end with the summer-weights.

* * *

I find in the *Medical Times* of March 17, 1849, the following "advertisement of a Doctor, on his arrival in the Brazils":

Estimable Brazilians! generous inhabitants of Rio Grande! the celebrated Doctor——, who, in different years, has visited Rio Grande, Porto Alègre and San Francisco has returned to your beautiful province with the firm determination to live and die among you! Generous inhabitants of Rio Grande! do not forget it is the same Doctor who amputated so many arms at Cassapara, so many legs at St. Gabriel, who excised so many jaws at Allegreto, extirpated so many testicles at Rio Pardo, so many breasts at Bargé! And, what is more, if you ask how many deaths followed these colossal operations, ask those who best can tell, and they will answer, Not one! Remember, also, it is the same Doctor who has enlarged the calibre of so many hundred contracted urethras without one relapse! Here, then, here I am! hasten to come to me! In less than seven days, I will make those that urinate in a stream as small as a hair, pass their water the size of a cable; I will treat homœopathically those who desire it; I will cure your fistulas without cutting; I will accept no money when patients die;—in a word I will especially treat all diseases, &c., &c.

Letters to the Editor

UNFORTUNATE NAMES OF HOSPITALS

SIR,—Lately an elderly man was investigated
inpatient in the throat department of a hospital
found to be suffering from carcinoma of the la
It was decided to transfer him direct to the C
Hospital for radiotherapy. His wife on arriving
one day found this telegram: "Bed available a
Cancer Hospital." Though she is a stolid w
she was very much upset. The diagnosis of cance
not been suggested to her before.

Is not there a good opportunity now to change
name and others (such as the Brompton Hospit
Consumption and Diseases of the Chest) which
cause alarm and despondency?

London. A

INFERTILITY DUE TO MECHANICAL FAIL OF OVULATION

SIR,—The failure of pregnancy to take place
appreciable percentage of apparently normal w
has led to many theoretical discussions on the cau
infertility. In spite of normal ovarian function, rev
by apparently normal basal body-temperature c
hormone-excretion studies, and normal histol
changes in the endometrium, mechanical failu
ovulation may occur regularly in some women
only occasionally in others.

Mechanical failure of ovulation occurs common
lower animals. Anyone acquainted with the tech
and interpretation of the Friedman test for preg
has observed two types of so-called "ovulation
positive reactions. Usually one sees large round b
hæmorrhagic follicles lacking apparent rupture
on the surface of the ovary. Endocrinologically,
corpora hæmorrhagica are "normal" in so far as
become functioning corpora lutea. They may, how
contain imprisoned ova, for ovulation, associated
the extrusion of the ovum, has not taken place. I
less common type of positive reaction, especially
an immature rabbit is used for the test, one may find
ovulation points. These appear as tiny almost pin
raised bright cherry-red papillæ. They are seldom
on the surface of corpora hæmorrhagica, and dev
when mature graafian follicles have ruptured and
charged their ova. The corpora hæmorrhagica that
form under these points after mechanical rupture of
ripe follicles are not so large or so readily seen as
corpora hæmorrhagica which develop in unrupt
follicles.

Possibly similar corpora hæmorrhagica and cor
lutea, not preceded by rupture of the follicle, ma
found in women. This would explain the occas
records of ovarian pregnancy. In such a case an ov
probably fertilised by a sperm that penetrates
ovarian capsule, and pregnancy develops without
ovum ever leaving its follicle.

It may be safely assumed that ovulation charact
by rupture of the mature graafian follicle occur
menstrual cycles in which conception takes place.
basal body temperatures of women who by this crite
have definitely ovulated have been analysed. It wil
remembered that body temperature in the few d
preceding ovulation in women is slightly but significa
lower than the temperature in the few days after ov
tion has taken place. This difference can be demonstr
in all women who appear to have normal cyclical ova
function.

The mean preovulatory temperature was 97·7
0·40°F in an unselected sample of 22 women un
investigation for infertility and in whom concept
took place during cycles for which basal body te
peratures were available. The mean postovulat
temperature was 98·51 ± 0·34°F. The mean preovulat
temperature was calculated from all of the temperat
records of the 22 women during the five-day peri
before the ovulatory rise began. The mean postovulato
temperature was calculated from all of the temperatu
recorded by the 22 women for a five-day period five da
after the ovulatory rise began. The difference betw

were rationed, it is true ; but anyone could obtain away from home which would make a couple of h restaurant repasts look very foolish. The applies in most other places in Europe.

is clear we shall not die from lack of fat. But, ed as it is with a low protein intake, and a low calorie diet, there is little doubt that general ncy is being impaired at a time when it is urgently

on, W.1. NEVIL LEYTON.

* We do not share our correspondent's belief that tzerland everybody can afford to eat regularly in ants.—ED. L.

UNDER TENSION

,—A Daniel has come to judgment ! THE LANCET g to resolve the international tension. And how. ems THE LANCET has discovered that England between two Great Powers and could act as or. One seems to have heard this wishful thought and not only expressed in English, but in French, gian, Swedish, and, until lately, in Czech. The *late* nes and the *late* Mr. Masaryk were most eloquent is subject. As a preliminary exercise in the rôle ator, it might be a good idea if one or two rs of the editorial staff tried their hand at recon- the conflict between Western bourgeois biology Marx-Leninist biology. They should visit Leningrad, ourse. For full measure, THE LANCET offers the ion that it takes all sorts to make a world. This kind of half-truth so common in proverbs. Tolera- and an accommodating attitude are admirable ies in the daily traffic of civilised life, but no one ir senses adopts this easy attitude towards another, repeatedly attempts to destroy him and who ims, fortissimo, his intention of going on trying he does destroy him. As THE LANCET is fond of bs I commend the wisdom of the one about the r and his last.

gton. P. D. H. CHAPMAN.

INDEX FOR FILM RECORDS

May I draw your attention to the paragraph s heading in your issue of Oct. 2 ?

e of 35 mm. film and camera for copying docu- journals, &c., should be referred to as "micro- " and not "photomicrography." The latter reserved for the photography of specimens through scope system.

filing system mentioned in your note is of little r the storage of filmstrips. It is, however, an nt file for 35 mm. negatives in short lengths (six ives), and in this sense could be used for storing ives of filmstrip. A filmstrip proper usually ns more than 20 frames in a continuous length

proper storage of filmstrips, as opposed to negatives, ffered difficulties in the past, and unfortunately the system mentioned does not provide the answer.

tminster Hospital Medical PETER HANSELL
School, London, S.W.1. Director of Medical Photography.

* We are grateful to Dr. Hansell for pointing our use of the word "photomicrography." As ds his other criticisms of our review, many teachers short lengths of the film with 2, 4, or 6 pictures se of their flexibility, which longer filmstrips lack. short filmstrips are useful in building up collec- of material and it is for such collections rather for the long filmstrip that good indexing is lly useful. Dr. Hansell rightly says that the od described is excellent for storing groups of up 6 negatives ; we think it equally useful for filing ps of up to 6 positives.—ED. L.

". . . truth which is unpalatable always calls forth persecu- The biologists suffer most, for biology intimately ts man and its truths are usually offensive to his emotions. physical sciences . . . do not generally raise emotional ts. . . . But the theory of evolution touches their pride they are not content to disbelieve it for themselves, but to suppress its acceptance by others."—*The Medical* r, Oct. 2, 1948, p. 143.

Obituary

GEORGE TRENCH WESTERN,

M.A., M.D. CAMB.

Dr. G. T. Western died on Oct. 5 at Chalford, Gloucestershire, to which he retired in 1938 from his appointment as physician in charge of the inoculation department of the London Hospital.

He was born in 1877, the son of the late G. A. Western of Shortlands, and he was educated at Monkton Combe and Pembroke College, Cambridge. There he took up rowing, and in 1901 he was spare man for the university boat. It remained one of his enthusiasms, and even when he retired he still took an oar and could exhaust many of his juniors. From Cambridge, where he took the natural sciences tripos in 1899, he went to the London Hospital, and after graduating in 1905 he was appointed one of Prof. William Bulloch's assistants—a distinguished group including Ledingham, Twort, McIntosh, Fildes, and Benians. Bulloch was at that time much interested in Almroth Wright's work on opsonins, and encouraged Western to develop it, giving him the charge of the inoculation department where he was to remain for the next 33 years. His published work included several papers on the treatment of puerperal septicæmia, and he made a considerable study of current methods of raising immunity to tuberculosis. During the first world war he collaborated with L. Rajchman in a special report to the Medical Research Committee (as it was then called) based on 878 cases of bacillary dysentery received from the Eastern Mediterranean.

Working as he did in Professor Bulloch's department in the medical college, Western did none of the routine bacteriological work of the London Hospital, but he was often called in when some special investigation was necessary. His heavy build in no way suggested the deftness he displayed in his bacteriological manipulations, and it came as a surprise to see him extract blood from the smallest vein with a skill that could not be surpassed.

Although a familiar figure to many generations of hospital men, he was less well known as a person—partly, no doubt, because of the isolation of his laboratory in the medical college, but also partly because of an austere and rather discouraging manner in the early days of acquaintance. Climbing was his great passion, and he went to Switzerland every year, except during the war, between 1899 and 1938. In these years he introduced several London Hospital men to climbing, and nothing gave him more pleasure than to see his pupils, after their apprenticeship, become members of the Alpine Club. One of them recalls him as "an exacting instructor, who would never allow carelessness of any sort. His slow and steady walk up to a hut gave an impression of reliability and endurance, but no indication of the ease and grace with which he climbed rocks, moving with effortless speed and rhythm. On off days he was a restful and delightful companion, and on these occasions there was no end to his vivid descriptions of climbs he had done in the past. In 1938, his last climbing year, he was still full of enterprise, and with two others, both of whom he had taught, he did several climbs he had not done before. Only few of those who knew him had the privilege of seeing him in this setting where his outstanding qualities of strength, reliability, and good companionship were so clearly shown."

When war broke out again in 1939 Western left his attractive home in the Cotswolds, and joined the Royal Army Medical Corps as one of its oldest lieutenants. As bacteriologist at the military Hospital for Head Injuries, at Oxford, he retained his London Hospital title of "Daddy Western," but acquired a new ancillary occurred with increase of *carrier*. When the amount of carrier injected was increased from 0·3 to 0·9 mg. the Schick-conversion rate rose from 12 to 72%; and when the amount was again increased to 7·5 mg. the conversion-rate was 91%.

This phenomenon can be accounted for if allowance is made for the normal distribution of the predisposition to immunity. This distribution accords with the law of normal distribution, or the law of Gauss-Laplace.[2] Applying these equations to Bousfield's figures, we see that the relationship between log. dose (mg. of $AlPO_4$ carrier) and percentage Schick-conversion rate expressed in probits is linear—in agreement with the Gauss-Laplace law (see figure). This statistical finding clearly confirms the consistent progress accomplished by Holt in devising his new diphtheria prophylactic.

Instituto Sieroterapico Italiano,
Naples.
E. CARLINFANTI.

HOSPITAL ADMISSIONS AND RECORDS

SIR,—The report from King Edward's Hospital Fund, reviewed on p. 578 of your last issue, will be welcomed by records officers, because it recommends the adoption of principles for which those actually engaged in hospital record keeping have been striving for a long while. It implicitly recognises that the job of records officer is a reality. It was, indeed, to achieve just such improvement as this report urges, that records officers up and down the country have formed an Association of Medical Records Officers. They have begun to put their own house in order by pooling their experience and by making arrangements for the more highly trained to provide educational courses for those who are not in touch with modern techniques and for new entrants to the service.

The recommendation that the hospital should have a records committee—elected by the medical committee from among its members and including the chief administrative officer of the hospital and a representative of the nursing staff—should greatly facilitate the work of the lay records officer by encouraging coöperation and providing a channel through which each member of the hospital team can acquaint other members with special difficulties.

The report remarks that there is at present no recognised training for records officers and urges that some regularised course should be agreed upon. An interim course has, in fact, been worked out by our association and a beginning has been made with weekend lecture courses at teaching hospitals at Bristol, London, Manchester, Cardiff, and Sheffield, with further courses to come at Leeds, Newcastle, and other centres. At these courses, to which hospitals within the appropriate regions are invited to send records staff, lectures and demonstrations are given on the following: hospital organisation; office management and selection of staff; appointments system; registration, admission, and discharge procedure; case-history routine; follow-up systems; forms, filing methods, indices, office equipment, and paper control; diagnostic nomenclature; and hospital statistics. It is hoped later to organise full-time training.

B. BENJAMIN
Chairman, Association of Medical Records Officers.

A SIMPLIFIED ROTHERA'S TEST

SIR,—The anticipation and prevention of severe ketosis is so important in the control of diabetes that a simple method of testing for ketone bodies is almost a necessity. The ferric-chloride test has been found unsuitable for use by patients, because (1) to do the test correctly may involve filtering off a precipitate and adding more ferric chloride, a procedure too complicated for many; (2) the colour of a positive reaction is often not properly recognised; (3) the test has many fallacies; and (4) in diabetics where the onset of ketosis is very rapid the test is somewhat too insensitive. Rothera's test is much more satisfactory, provided the patient is warned of its great sensitivity, but the procedure is beyond the mental capacity of some—particularly those who through carelessness or lack of intelligence are liable to slip into a dangerous ketotic state.

To overcome these disadvantages a "powder" for ketone bodies has been evolved. The most s factory composition of the powder has been found t sodium nitroprusside 0·5%, anhydrous tribasic so phosphate 12·5%, and ammonium sulphate The exact proportions are not important, but the ab mentioned mixture gives a powder which does develop any interfering colours. It is important, ever, to ensure that the salts are dry before they mixed. Some of this powder has now been kept corked bottle for eight months and is still perf satisfactory. Some batches deteriorated where adeq care was not taken to ensure that the sodium phosp was really dry.

The test is carried out by moistening a small p the powder with a drop of urine, the colour being at the end of 3–5 min., a procedure well within capabilities of the poorest intelligence.

It may be objected that the test is too sensiti 0·02% of acetone just produces a purple colour 5 min., and the same concentration of diacetic produces a definite purple colour. We feel, how that this sensitivity is an advantage if the patient told that the final colour must be very dark before need report. To obviate any mistake, paper of the colour for comparison is being prepared. The dev ment of the ketosis can be watched by the patient several days, and so adequate warning of the cond is obtained. Those who are sufficiently intelligent make appropriate alterations in dosage of insulin a their diet.

For the past eight months all diabetic patien one of us (G. A. S.) have been instructed in the use o powder. Without exception they have all found the easy to perform, and none are confused by it. It is rare that even a weak positive result is obtained three patients have reported to hospital because strong positive result (confirmed in hospital), so ena the ketosis to be corrected without difficulty.

Armed with this simple test, the diabetic pa should be ensured against going unwittingly in dangerous diabetic coma.

G. A. SMART
Lecturer in Medicine, Bristol Unive
G. H. DARLING
Chief Pharmacist, United Bristol Hosp

DIETARY FAT

SIR,—The question of minimum fat requirement the diet, raised in your issue of Sept. 18, is of g interest. But it cannot be solved simply by ex ments which go to show whether there is a lack so that it is demonstrable by chemical analysis. N statistical evidence of increased disease incidenc much value. By the time such evidence is avail we all know too well that a deficiency exists.

Neither can lack of one factor be divorced consideration of others. For instance, though carbohydrates are probably adequate, our pro intake is low.

In this country we have been strictly rationed eight years now. Before this, limitation of food unknown; which means that, apart from phy deficiency, the psychological factor must be taken consideration. Though this latter is occasionally m tioned it is rarely given the prominence it deserves.

Some animals are herbivorous by nature; but mos us prefer to eat meat. In the same way the majo not only like food which requires fat for cooking, they miss the staying power of the fatty food fac the last to be digested. Indeed, it is admitted t people feel hungry sooner than they used to do. race that does not consume much fat presumably can have developed that particular desire. Also, it is kno that dwellers in hot countries do not require fats in s quantities as those who live in temperate or cold areas

So far as Europe is concerned experience of countries since the war[1] makes me certain that Brit is the worst off, apart from parts of Germany. T Swiss have complained to me that I have misrepresent their fat and meat intake. But this is not the ca and on histamine and acetylcholine. More and more appear from subsequent work that adrenaline, hista- and acetylcholine were three substances which the body for many different purposes. It now appeared that the of a large number of chemical substances in the body to modify or interfere with the action of adrenaline or or acetylcholine. It seemed possible that local and analgesics were substances which antagonised action of acetylcholine at sensory nerve-endings, or in parts of the central nervous system and that the power of es to lengthen the refractory period of heart muscle be related to their antagonism to acetylcholine in the of cardiac tissue.

---

[2] See Carlinfanti, E. *J. Immunol.* 1948, 59, 1, and *Ibid* (in the press).

[1] Leyton, N. A Survey of our Subnutrition. *Med. Pr.* 19 218, 331.

interrelation of properties of local anæsthetics, spasmo- and analgesics made it worth examining all compounds to exert one of these properties for its possession of others. A substance introduced as a local anæsthetic be, for example, a still better spasmolytic. It was because anti-histamine substances possessed the properties that they produced side-effects. If they were analgesics it was not surprising that they caused mental and depression, and if they were atropine-like it surprising that they caused dryness of the mouth.

other way in which the grouping together of many es as fundamentally the same was useful was that it some order into the long list of apparently unrelated alkaloids. The similarity in many properties of atropine, and quinine, and of conessine from kurchi bark suggested points of biochemical similarity, thus towards an understanding of relationships. These surely justified the pharmacologist studying the of acetylcholine, histamine, and adrenaline in the body. studies were likely also to advance the practically subject of chemotherapy.

ity of London

E. M. Crook, PH.D., gave the first of four public lectures College, Gower Street, W.C.1, on the Electron and its Biological Applications. The other lectures on Mondays, Oct. 18, 25, and Nov. 8, at 4.45 P.M. Nov. 5, at 5 P.M., Prof. G. Levi, of the University will deliver a lecture on Relations of Interdependency various parts of the Nervous System in the Embryo Adult.

Cruickshank has been appointed to the chair logy at St. Mary's Hospital medical school as from

shank, who is 49 years of age, was educated at Strichen school and the University of Aberdeen where he graduated honours in 1922. For the next two years with an Anderson fellowship he worked at Aberdeen and at where he later became resident medical officer at the for Children and assistant medical officer at Belvidere Diseases Hospital. In 1925 he graduated as M.D. honours. He held the McRobert lectureship in cancer Aberdeen in 1927, and in the same year he was the of the Hutchison prize for his essay on intestinal In 1928 he was appointed lecturer in bacteriology of Glasgow, and he also held the post of bacterio- the Glasgow Royal Infirmary. In 1936 he came to London to the group laboratory at the L.C.C. North-Western Three years ago he was appointed the first director of laboratory of the Public Health Laboratory Service at and during the past three years he has also been acting teacher at the London School of Hygiene. In Cruickshank delivered at the Royal College of Physicians lectures on Pneumococcal Infections. He was a lecturer in 1943 and gave the Frederic Still lecture on in Infancy to the British Pædiatric Association in 1945. published work includes papers on the biology of the vagina, infection of burns, staphylocoagulase, diagnosis of pertussis, spread of infection, and the control of dust-borne strep- infections. He was joint editor of THE LANCET manual *of Common Fevers* and a sectional editor of *Recent Advances Pathology*. In 1946 he was elected F.R.C.P.

rsity of Leeds

annual dinner for past and present students of the school will be held at the Great Northern Hotel, on Friday, Nov. 26, at 7.30 P.M. Dr. J. T. Ingram and Lord Moran will be the principal speaker. may be obtained from the secretary of the Students' Council at the school before Nov. 14, 1948.

ical Practitioners' Union

Bruce Cardew has been appointed general secretary to Practitioners' Union and editor of the *Medical* in place of Dr. A. Welply, who has retired.

Royal College of Physicians of London

A course of lectures will be given at the college, Pall Mall East, S.W.1, at 5 P.M. daily from Nov. 2 to Dec. 17. Applications should reach the registrar by Oct. 25.

Westminster Hospital and Medical School

The annual dinner for past and present students was held in London on Oct. 2 with Sir Arnold Stott in the chair. The speakers included Mr. G. H. Macnab (dean of the Medical school), Mr. H. E. Harding (subdean), and Sir Adolphe Abrahams.

Northern Ireland Health Service

In Northern Ireland about $1^1/_4$ million people—93% of the population—have placed their names on doctors' lists under the health scheme. These figures have been given by Mr. William Grant, minister of health and local government, who said that 730 doctors had so far joined the service.

National Marriage Guidance Council

Miss Phyllis Bottome will deliver the Donald Gillies lecture at the Royal Society, Burlington House, London, W.1, on Wednesday, Oct. 20, at 6 P.M. She is to speak on Love and Marriage. Sir Eardley Holland will be in the chair.

Scottish Society of the History of Medicine

A meeting of this society will be held at the Royal Faculty of Physicians and Surgeons, 242, St. Vincent Street, Glasgow, on Wednesday, Oct. 20, at 5.30 P.M., when Prof. J. D. Mackie will speak on the History of Glasgow, and Mr. A. L. Goodall on the History of the Faculty.

St. George's Hospital

Dr. Anthony Feiling and Dr. Desmond Curran are to give a series of lecture-demonstrations in neurology and psychiatry at the medical school during the autumn term on Thursdays at 4.30 P.M. They are open to all doctors and senior students.

Parentcraft in the Home

The National Association of Maternity and Child Welfare Centres and for the Prevention of Infant Mortality is holding a conference on this subject at the Y.W.C.A., Great Russell Street, London, W.C.1, on Friday, Oct. 22, at 10.30 A.M. Dr. Leslie Housden will be in the chair.

Royal Society of Medicine

Norman Gamble Fund.—The committee of award will shortly consider applications for grants from this fund in aid of research in otology. Applications should reach the secretary of the society, 1, Wimpole-street, London, W.1, from whom further particulars may be had, not later than Nov. 25.

King Edward VII's Hospital for Officers

Queen Mary is reopening this hospital at Beaumont House, Beaumont Street, London, W.1, today, Oct. 15. The hospital has 2 wards of five beds and 2 of two beds, where nursing and maintenance will be free. There are also 17 single rooms where a charge will be made. Patients make their own arrangements with their physicians and surgeons. Regular and retired officers of the three Services are eligible for admission; also all temporary officers who fought in the 1914–18 or 1939–45 wars provided they become subscribers. Applications should be made to the house-governor.

Alamein Village Settlement

In his address to students at the annual prize-giving of Charing Cross Hospital on Oct. 7, Field-Marshal Viscount Montgomery of Alamein referred to the Alamein Village Settlement intended largely for men discharged from the Services because of tuberculosis. It will be run, he said, in conjunction with the existing village settlement at Enham, near Andover, Hants, which was established for disabled men after the first world war. It is hoped that accommodation will be found for 500 ex-Service personnel who will be taught a trade and given the opportunity of partaking in the industries of Enham. There will be a hostel for the men without families, cottages for those with families, a village club, a church, and a hospital.

reputation as a most efficient and economical, if autocratic, messing officer, who kept bees and grew vegetables in the hospital garden—and treated everyone alike regardless of rank. As an old member and treasurer of the Cambridge Graduates Medical Club he was to have attended its meeting last week.

He married in 1907 A. S. Carter, and had a son and two daughters.

Diary of the Week

OCT. 17 TO 23

Monday, 18th

Royal College of Physicians, Pall Mall East, S.W.1
3 P.M. Dr. F. M. R. Walshe, F.R.S.: Structure of Medicine and its Place among the Sciences. (Harveian oration.)
Royal College of Surgeons, Lincoln's Inn Fields, W.C.2
5 P.M. Prof. D. W. Smithers: High-voltage X Rays in the Treatment of Malignant Tumours at a Depth.
Society of Apothecaries, Black Friars Lane, E.C.4
5 P.M. Prof. D. F. Cappell: Clinical Importance of the Rh Factor.
Hunterian Society
8.30 P.M. (Talbot Restaurant, London Wall, E.C.2.) Dr. G. R. Mather Cordiner: Rôle of Radiology to the Peptic Ulcer Problem. (Presidential address.)

Tuesday, 19th

Society of Apothecaries
5 P.M. Mr. H. Osmond-Clarke: Rehabilitation of the Physically Injured.
Institute of Dermatology, 5, Lisle Street, W.C.2
5 P.M. Dr. F. Ray Bettley: Papular Dermatoses.
Society for the Study of Addiction
4 P.M. (11, Chandos Street, W.1.) Dr. J. Yerbury Dent: Treatment of Anxiety and Addiction by Apomorphine.

Wednesday, 20th

Royal College of Surgeons
5 P.M., Prof. J. Paterson Ross: Surgery of the Sympathetic Nervous System.
Society of Apothecaries
5 P.M. Dr. Macdonald Critchley: Modern Treatment of Some Neurological Disorders.
Harveian Society
8.15 P.M. (26, Portland Place, W.1.) Dr. Samuel Oram: Pulmonary Embolism.
Royal Institute of Public Health and Hygiene, 28, Portland Place, W.1
3.30 P.M. Dr. Peter Henderson: Epilepsy in Children.
University of Glasgow
8 P.M. (Department of Ophthalmology.) Dr. Byron Smith: Plastic Surgery of the Eyelids.

Thursday, 21st

Royal College of Surgeons
5 P.M. Mr. P. H. Mitchiner: Surgery of Sepsis.
Society of Apothecaries
5 P.M. Dr. R. R. Trail: Treatment of Pulmonary Tuberculosis.
Royal Society of Tropical Medicine and Hygiene, 26, Portland Place, W.1
7.30 P.M. Dr. J. T. Duncan: Epidemiology of Fungus Diseases. Dr. Isaac Muende: Treatment of Fungus Diseases.
British Orthopædic Association
10.30 P.M. (Queen's University, Belfast.) Prof. George Perkins: Painful Shoulder.
2 P.M. (Whitla Medical Institute, Belfast.) Short papers.
Honeyman Gillespie Lecture
5 P.M. (Edinburgh Royal Infirmary.) Mr. Joe Pennybacker: Intracranial Tumours in the Aged.

Friday, 22nd

West London Medico-Chirurgical Society
8.30 P.M. (South Kensington Hotel, 41, Queen's Gate Terrace, S.W.7.) Dr. W. S. C. Copeman: West London Worthies—a Retrospect. (Presidential address.)
Middlesex County Medical Society
3 P.M. (Hillingdon Hospital, Uxbridge.) Miss J. Morgan: Report on 450 Cæsarean Sections. Mr. K. S. Mullard: Carcinoma arising in Segmental Bronchi.
British Orthopædic Association
9.20 A.M. (Whitla Medical Institute, Belfast.) Short papers.
11 A.M. Mr. S. A. S. Malkin: Presidential address.
2 P.M. (Royal Victoria Hospital.) Clinical demonstrations.

Saturday, 23rd

Nutrition Society
10.30 A.M. (Royal Society of Arts, John Adam Street, W.C.2.) Discussion on Anti-vitamins in Food.
Biochemical Society
11 A.M. (London School of Hygiene, Keppel Street, W.C.1.) Symposium on Partition Chromatography and its Application to Biochemical Problems.
British Orthopædic Association
9.20 A.M. (Whitla Medical Institute, Belfast.) Short papers.

Notes and News

MEDICAL RECRUITS

The Central Medical War Committee has been infor that, on the recommendation of the Medical Priority C mittee, the Minister of Health, with the concurrence of Secretary of State for Scotland, has decided that the em gency arrangements under which a young practitioner li for military service is recruited after six months' tenure o "A" post will cease at the end of October. Young pr tioners completing their tenure of "A" posts on or Nov. 1, and selected for appointment to "B2" posts, wi granted deferment of call-up in accordance with the re tions in operation before the introduction of the emerg arrangements last July.[1] Hospital authorities are t informed by circular letter of this change in proce There is, however, no change in the arrangement under w *young practitioners approaching the age of 26 on qualifi* are recruited before their 26th birthday, even if this prevent their completing an "A" post or occupyin "A" post at all.

THE TEAM SPIRIT IN HOSPITAL

In an address opening the new session of the Royal Hospital, London, on Oct. 1, Mr. L. E. C. Norbury, s *surgeon to the hospital and a vice-president of the* F College of Surgeons, spoke on the importance of team-w In a hospital, he said, the work of each department is a n to a common end, and each department is an essential in the team. On entering the medical school the st is initiated into the team, and the team spirit shoul inculcated from the earliest days—though the proces initiation may be unexpected and something of an or

In Mr. Norbury's opinion more use should be made o services of professors and teachers of the preclinical sub as members of the team, in discussions and demonstrat He recalled a series of lecture-demonstrations, held years ago at the Royal Free, in which clinical and precl teachers dealt with the subject from their particular a "To my mind such a discussion by various members team, and the pooling of knowledge, is of far greater pra value to all concerned than a stereotyped lecture. pendulum is already swinging in this direction, and I forward to the day when the old formal series of lecture be replaced entirely by lecture-demonstrations along lines indicated. It is the practical application of know which should be instilled into the mind of the student. textbook can be studied at home and at leisure."

In a properly conducted team there must be com service and common loyalty, and in arriving at a satisfac plan of campaign there must be discussions and consultat with free expression of opinions. Such cultivation of team spirit was essential for progress in medical sci In a recent speech Mr. Herbert Morrison had said: "I could bring into every factory and mine and farm and w shop the spirit and enthusiasm that the ordinary man bro to team games half our troubles would be over," and t sentiments, Mr. Norbury believed, could usefully be ap to medicine. In a well-appointed team there must, more be time for relaxation and social enjoyment: its mem must "work in harmony both socially and intellectuall order to produce the optimum results."

PHARMACOLOGICAL RELATIONSHIPS

The Society of Chemical Industry has formed a chemicals group, and at the first meeting, held in Lo on Oct. 5 with Sir Jack Drummond, F.R.S., in the chair inaugural address was delivered by Dr. J. H. Burn, F professor of pharmacology in the University of Oxford. said he had always believed that the university wo should be willing to assist industrial laboratories if he co as a matter of public service. One of the contributions m by university pharmacological laboratories to advance in fine chemical industry was the introduction of method biological standardisation, and tribute was due to Sir He Dale in gaining acceptance for the principle of compara methods and of the necessity for international standa

Another contribution, he said, stemmed from the clas work of Dale and Laidlaw, and their chemical colleagues G Barger and Ewins, on adrenaline and sympathomim

MENINGOCOCCOSIS

A PROTEAN DISEASE*

H. STANLEY BANKS
M.D. Glasg., F.R.C.P., D.P.H.
SICIAN-SUPERINTENDENT, PARK HOSPITAL, HITHER GREEN

RECOGNITION of the protean nature of infections is y slow. The dominant clinical form may long be ought of as the complete disease. In most cases the cept soon becomes widened by inclusion of the more viously related clinical forms; but it is only after tracted clinical observation and laboratory study t the rarer forms are revealed in their true relation the disease complex. This ever-widening conception disease has long been familiar in tuberculosis and ilis. We are witnessing it today in glandular er and poliomyelitis. I think it is no less true of ningococcal disease.

Cerebrospinal meningitis," "epidemic meningitis," d "cerebrospinal fever" are terms representing successive expansions of the idea of this disease. The aterhouse-Friderichsen syndrome and scattered cerebral ppuration represent later accretions. Chronic meningocal septicæmia was firmly added only during the late The encephalitic forms, the hæmorrhagic and nonmorrhagic adrenal forms, the pituitary and other tastatic lesions are all comparatively recent concep. "Cerebrospinal fever" is a designation no longer quate for the disease as a whole. "Meningococcal ase" is an inclusive term but somewhat colourless. protean nature of the disease and its broad pathology n to justify "meningococcosis" as a generic name for forms of the disease on the analogy of tuberculosis, dinosis, and the like.

The basis of these lectures is a series of 706 consecutive admitted to the Park Hospital between Jan. 1, and June 30, 1947, a period of stabilised treatment the more active sulphonamides, and, in the later with systemic penicillin in a few selected cases. treatment was not used in any case, having been rejected as unnecessary during the experimental period of chemotherapy in 1937–38.

The series is mainly a civilian one of the usual varied age-distribution from infancy to over 70 years of age, but contains a number of Service cases which slightly overload the young adult groups. This is balanced, however, by the higher than normal incidence of older persons admitted during the war and the evacuation, when many young persons were absent from London. The period includes pre-epidemic, epidemic, and post-epidemic phases. The greatest pressure of the epidemic phase came in the first four months of 1940, when 120 patients were admitted, of whom 12 died, 6 being infants —a case-fatality rate of 10%. This is somewhat higher than the case-fatality rate for the whole period (7·36%).

TABLE I—RESULTS IN 706 CONSECUTIVE CASES OF MENINGOCOCCAL DISEASE ADMITTED TO PARK HOSPITAL 1939–47

Age-group (years)	No of cases	No. of deaths	Fatality-rate (%)
0–1	76	18	23·7
1–2	43	2	4·6
2–3	47	2	4·2
3–4	45	3	6·6
4–5	31	2	6·4
5–15	90	3	3·3
15–25	171	6	3·5
25–35	92	5	5·4
35–45	45	4	8·8
45–55	36	2	5·5
55–65	19	2	10·5
65–75	11	3	27·2
Total	706	52	7·4

It should be noted that no case has been excluded from the series, even though the patient was moribund on admission.

Table I shows the age-incidence and fatality in single years up to 5 years of age, and in ten-year periods thereafter. This illustrates some general principles of the epidemiology of the disease: (1) there are far more cases in infants under a year than in any other single year of age; (2) incidence declines with age, except for the period 15–25 years, which contains more cases than the previous decade; (3) after the age of 35 there is a sharp drop, and after the age of 55 another and still sharper drop in incidence; and (4) case-fatality rates are high only at the extremes of life, the curve of mortality from infancy to old age being cup-shaped, with its lowest level between 15 and 25 years.

Fig. 1 shows the curves of notifications of cerebrospinal fever during 1936–45 and indicates the general epidemiological background of the series. The years 1940–42 were the epidemic years, each with a characteristic peak incidence in March. In the later years there was no well-defined peak but about twice as many cases in the first half of the year as in the second, a form of curve resembling that of the prewar years but two or three times as high, both in winter and in summer. The force of the 1940–42 epidemic did not in fact expend itself until about June, 1947.

ORDINARY FORM

The habitat of the meningococcus is the nasopharynx, where the organism mostly leads a saprophytic or semi-saprophytic existence. Meningococcal infection of the nasopharynx is mainly subclinical. Under exceptional conditions the organism becomes invasive and finds its

Planning Forum

The autumn series of lectures to be held in the Planning Centre Hall, 28, King Street, Covent Garden, London, W.C.2, includes discussions on the Kinsey Report by Mr. David Mace, PH.D., Dr. Fred Grundy, and the Rev. J. Leycester King (Oct. 27); on Population and Emigration by Dr. David Glass, Prof. Brinley Thomas, and Mr. R. J. Goodman (Nov. 11); and on Work and Health by Dr. R. S. F. Schilling, Mr. Brian Bunch, A.R.I.B.A., and Dr. John Burton, with Prof. J. M. Mackintosh in the chair (Nov. 24). The lectures are held on the fourth Wednesday and second Thursday in each month at 6.15 P.M., and further particulars may be had from the centre.

S.M.A. on Health Centres

The council of the Socialist Medical Association has passed a resolution which welcomes the recognition by the council of the British Medical Association of the need for health centres, and continues:

> The Socialist Medical Association supports the urgent demand put forward for an experimental trial of different types of health centre in varying areas, but is strongly opposed to the view that widespread development of health centres should not be commenced until after such experiments are completed. The further development of general practice depends on health centres, and these, in accordance with the Act, must be set up and properly equipped by the local health authorities, and not left to individual groups of practitioners whose association would not be under democratic control.

Minister on Health Service

On Oct. 7, addressing the first annual meeting of the Executive Councils' Association (England) of the National Health Service, Mr. Aneurin Bevan, Minister of Health, again appealed to the public to use the service prudently, intelligently, and morally; he described it as a test of the maturity of the British people. As reported in the *Times*, he went on to speak as follows of the general practitioner's responsibility. "Over-prescribing can be as bad as under-prescribing. Some general practitioners are very conscious of the impressiveness of long lists of drugs in their prescriptions on the psychology of their patients. We want the general practitioner to prescribe what he believes is necessary, and put nothing in his way—but we want to impress upon him that it is not a good thing to evoke merely a psychological response by prescribing too expensive drugs." In the N.H.S., he said, the number of prescriptions is approaching twice what it was under National Health Insurance. At the present rate over 140–150 million prescriptions would be dispensed annually.

On Oct. 6 the Minister of Health met the chairman of boards of governors of teaching hospitals, regional hospital boards, and hospital management committees. This was in response to a personal invitation from the Minister, who is anxious to make regular contact with as many as possible of those who now share responsibility for running the National Health Service. Mr. Bevan stressed that their responsibility lay, first and foremost, with the patient, and this must never be forgotten or overlooked.

Cambridge Graduates Medical Club

This club held its annual meeting at Downing College on Oct. 6. Presiding over some 65 members at the dinner, Mr. W. H. C. Romanis recalled that from 1930 until the war the club met once a year at Cambridge. Sir Lionel Whitby, master of Downing and regius professor of physic, who was the principal guest, said that the club's function was mainly social: it provided an opportunity to revisit Cambridge and meet old friends. While Oxford had become an industrial city, Cambridge remained an overcrowded market town, without the advantages or the disadvantages of wealth. The medical school, full to overflowing, was incomparably more difficult to enter than in "our day," and the examinations were so much more difficult that he was glad to be on the right side of the table. The main innovation was the institution of a postgraduate school. Having secured recognition of Addenbrooke's as a teaching hospital, the next task had been to develop departments specially appropriate to Cambridge—first in radiotherapeutics (associated with physics) and in experimental medicine (associated with physiology and biochemistry). The new department of human ecology was not only making epidemiological and statistical studies of the peculiar problems of the fenland but had also undertaken the preventive medical care of undergraduates. He h in due course to see departments of pædiatrics ar hæmatology. The policy adopted was to take one step time, obtaining funds through normal channels. It rem to be seen whether Cambridge would ever have a full u graduate medical school; but certainly it could not till Addenbrooke's was rebuilt—for which there were sch involving a 100-acre site and 1200–1500 beds. In concl Sir Lionel Whitby spoke of the difficulties to be expect the scale of academic salaries remained at its present so low in relation to the rewards to be expected in ordinary specialist practice.

Colonial Medical Research Studentships

The Secretary of State for the Colonies has institu limited number of these studentships for graduat medicine and cognate sciences, who wish to prepare t selves for research work in tropical medicine and re subjects. It is the intention that students satisfact completing their courses shall be offered posts in the pro Colonial Research Service. Application should be r through the head of the candidate's department, tc Secretary, Colonial Medical Research Committee, c/o Res Department, Colonial Office, Sanctuary Buildings, Great S Street, London, S.W.1.

Dr. D. J. A. Alban-Jones has been awarded scholar by the Belgian and Netherlands governments throug British Council to study obstetrics and gynæcology. He work at the Hôpital St. Pierre in Brussels for eight mo and he will then spend four months in Amsterdam.

Following representations by the Medical Defence U Messrs. Silten Ltd., the manufacturers of 'Leucotr have expressed regret that a pamphlet advertising product quoted from a book by Prof. L. S. P. Davidson Dr. J. J. R. Duthie, without authority and in such a as to give the impression that these authors advocate use of leucotropin and had composed the pamphlet.

British Drug Houses ask us to state that free copies of *Guide to the B.P. 1948* will be sent to doctors who app their offices at Graham Street, City Road, London, N.1.

Births, Marriages, and Deaths

BIRTHS

CANE.—On Oct. 4, in London, the wife of Dr. C. S. Cane—a

CUMMING.—On Sept. 30, in Edinburgh, the wife of Dr. R Cumming—a son.

FRANKLIN.—On Oct. 4, in London, the wife of Dr. John Fra —a daughter.

GINSBORG.—On Oct. 4, in London, the wife of Dr. S. Ginsbo a son.

HART.—On Oct. 5, in London, the wife of Dr. F. D. Har daughter.

LANE.—On Oct. 7, the wife of Dr. Roger Lane—a daughter.

ROBINSON.—On Oct. 2, at Slough, Bucks, the wife of Dr. A Robinson—a son.

ROGERS.—On Oct. 7, in London, the wife of Dr. John Roger daughter.

RUSSELL.—On Oct. 5, at Nottingham, the wife of Dr. Ma Russell—a son.

SWINNEY.—On Aug. 28, in Albuquerque, New Mexico, the wif Mr. John Swinney, M.C., F.R.C.S.—a son.

MARRIAGES

HEWLETT—BARRACLOUGH.—On Sept. 29, at West Byfleet, He Reynardson Hewlett, lieut.-commander, R.N., to Patr Mary Barraclough, M.B.

DEATHS

DINGLE.—On Oct. 2, Frederick Robert Dingle, M.R.C.S.

HANNAY.—On Oct. 5, in London, Robert Strickland Hann C.B., C.M.G., D.S.O., L.R.C.P.E., major-general, late R.A. retd, aged 77.

HEMSTED.—On Oct. 7, at Kintbury, near Newbury, Berks, Edm Spencer Hemsted, M.R.C.S., aged 78.

MCCARTHY.—On Oct. 3, at Sidmouth, John McDonald McCart M.B. Camb., colonel, R.A.M.C. retd, aged 75.

MALCOLM.—On Oct. 6, in Edinburgh, John Wright Malcolm, O.B. M.C., M.B. Edin., lieut.-colonel, R.A.M.C. retd, aged 56.

PORTER.—On Oct. 4, at Bristol, Charles Porter, M.A. Oxfd, M.R.C

ROBERTS.—On Oct. 7, in London, Alexander Boyd Robert M.D. McGill.

STEPHENS.—On Oct. 8, at Newquay, Cornwall, William Jo Stephens, M.R.C.S., aged 82.

WESTERN.—On Oct. 5, at Chalford Hill, Stroud, George Tre Western, B.A., M.D. Camb.

way into the blood-stream and meninges to produce the ordinary form of the disease. This is especially liable to happen with group I strains during an epidemic and with group II strains in infants. Such activity is preceded or accompanied by overt nasopharyngitis in about a third of the cases, but the rôle of the meningococcus in the production of this nasopharyngitis is uncertain, since the common organisms of the upper respiratory tract obscure the picture. A few instances have, however, been recorded of pure cultures of meningococcus in tonsillitis (van Rooyen and Morris 1941), and in nasopharyngitis (Allison 1947). Irrespective of the presence or absence of clinical nasopharyngitis, the same type of organism as that in the spinal fluid may be isolated from the nasopharynx within a day or two of onset of symptoms and it usually then disappears (Flack 1917).

The sequence of events in the ordinary form of the disease is generally held to be: (1) nasopharyngeal infection (usually subclinical); (2) bacteriæmia; and (3) meningitis. Fairbrother (1947) revived the older theory of direct infection of the meninges from the nasopharynx via perineural pathways. This theory is difficult to reconcile, however, with the numerous proved cases of premeningitic meningococcæmia in fulminating and ordinary forms and with ameningitic chronic meningococcal septicæmia. It must be admitted that the exact mechanism by which the organism passes into the blood-stream from the nasopharynx is unknown. Clinical histories and routine blood-cultures suggest that the premeningitic bacteriæmia is usually short—a matter of minutes or hours in the ordinary form. In rare cases it has been observed for two or three days. A papulo-petechial rash is present at this stage in 25–50% of the cases.

The ordinary form is encountered in fully 90% of all clinical cases in epidemic times and probably over 95% in non-epidemic times. It is so well known that it need receive no further attention here. I wish to deal more particularly with the rarer forms of the disease, some of which are less easily recognised and differentiated. Recognition of these syndromes is important in our understanding of the disease, and their early diagnosis is of the utmost importance in treatment.

CHRONIC MENINGOCOCCAL SEPTICÆMIA

Though the chronic septicæmic form was first described as early as 1902 it received little attention until the epidemic of 1940–42, when numerous cases were observed among British troops in France and in the civilian population of Great Britain. It still crops up occasionally, especially in the meningococcal season. It should be borne in mind in all states of intermittent pyrexia accompanied by crops of spots. The clinical picture is usually very characteristic: (1) bouts of pyrexia every two or three days with or without rigors and sweating, sometimes suggesting malaria; (2) recurrent crops of papules, sometimes with petechial centres, on trunk and limbs; (3) raised circular erythematous areas resembling erythema nodosum; and (4) occasional rheumatic accompaniments in the form of pains or swelling of joints, and pains in muscles, tendons, fasciæ, and bones. Priest (1947) described one case with febrile bouts extending over several months in which there was no rash. An attempt should be made to confirm the diagnosis by blood-culture, but this may be negative, even after repeated attempts, in 25–50% of the cases. In pre-sulphonamide days the condition sometimes lasted for months or even years before burning itself out or ending in meningitis. It gets little chance to do so now, for even a few doses of sulphonamides end the condition at once.

ACUTE DIFFUSE ENCEPHALITIC SYNDROME

In severe cases of the ordinary form the patient is often stuporous or semicomatose but resents, and sometimes violently resists, any attempts to treat disturb him. In contrast with this common picture is the relatively rare development, early in disease, of deep coma, associated with complete of response to gross stimuli, such as pinching and pullin the patient about in bed. Even reflex swallowing may b absent, but this is unusual. Most of these cases the ordinary form for 24 hours or so and then into deep coma suggesting a rapid increase in intra pressure. Breathing is laboured or stertorous. involvement is indicated by extensor plantar reflexes, and by pareses. A slight papillœdema is commo There is some stiffness of the neck and back associate with the purulent meningitis, but otherwise the musc may be flaccid. A petechial eruption, usually scanty, may be present, or there may be no rash. Response sulphonamide treatment is negative or very slow, the condition being often fatal in three to seven days return of consciousness.

In the absence of any other cause of coma, such that associated with glycosuria with severe ket or concurrent true diabetes, this clinical syndrome the "acute fatal type" of the older writers. Banks an McCartney (1942) found, in some of these cases, chara teristic histological lesions in the brain and cord whi might be correlated with the deep coma and oth clinical symptoms, and described such cases as the "acu diffuse encephalitic syndrome."

In my series of 706 patients there were 13 consider to belong to this category, of whom 6 recovered a 7 died. Only 4 of the fatal cases could be investigat histologically, but in all 4 the characteristic lesio were found in the brain and cord, varying in according to the duration of the comatose state. Th lesions consisted not only of congestion and œdema b also of widespread thrombosis in, and hæmorrha around, small vessels and of perivascular leucocyt infiltration, sometimes with gross deposition of fibr Purulent meningitis was always present, but this usually clearing or had almost cleared as a result of sulphonamide treatment. In the 2 more protracted cas the perivascular leucocytic infiltration amounted places to dense zones of polymorphs, suggesting that a abscess was beginning to form. Besides these vascular and perivascular lesions there were also deg erative changes in the neurone cells. The lesions we diffusely spread in the brain stem, cerebral hemisphere cerebellum, and cord (figs. 2–6).

It is somewhat surprising that little confirmato evidence of this syndrome has, to my knowledge, sinc been published, except a typical example by Wartma and Hænger (1944), who, using Spielmeyer's myelin stain showed that the pale areas around the hæmorrhagic fo in the brain were due to displacement of the myelinate nerve-fibres, *and that there was no primary* demyelinatio They point out that the absence of demyelinatio

Adrenal Type

This syndrome is represented in the series by 13 ts of whom 8 died and 5 recovered. There were infants under 1 year, 6 children aged 1–6 years, and ults aged 19–34. All 3 infants died, but 4 children l adult recovered. The diagnosis in the recovered could, of course, only be presumed from the ptoms.

The main symptoms in this syndrome were a sudden t of fever, with fretfulness or malaise, and the rapid arance of a generalised petechial rash, which soon e purpuric. In most cases the purpura became ve, and large cyanotic areas could also be seen in skin. With the development of purpura, peripheral tory failure set in, the blood-pressure being low unrecordable. Meningococci were present in blood- e and often in films of the peripheral blood. Signs eningitis were generally absent on first examination tended to appear later. In contrast with the phalitic type the mental state was clear almost to end. The cardinal signs of the syndrome were the ive purpura, the low blood-pressure, and the clear tal condition, all associated with an overwhelming ticæmia.

At necropsy the brain and meninges showed little e than congestion; the most conspicuous lesions e found in the suprarenal glands—usually bilateral orrhage of various degrees, starting in the inner reticular layer of the cortex, but often extending rds to the medulla and outwards almost to the phery of the cortex, so that much of the gland was troyed. When the hæmorrhage was massive, some of large medullary veins might be thrombosed. Many the cortical cells were out of alignment and showed nerative changes and even necrosis. This was easily seen in the actively functioning outer or erular layer of the cortex.

ks and McCartney (1943) published illustrations ous types of hæmorrhagic adrenal lesions, from the stage to massive hæmorrhage accompanied by osis of venus sinuses and complete destruction gland. Some of the intermediate types showed ly hæmorrhage but also well-marked degenerative ges in the cortical cells. The same workers, however, illustrated non-hæmorrhagic adrenal lesions which t be associated with severe adrenal dysfunction. e included gross degeneration of cells of the erular cortex with complete disorganisation of the cture of the cortical cords, as well as gross œdema of whole gland and foci of leucocytic infiltration tered through the gland. One of these photomicro- phs is reproduced here (fig. 8). It shows degeneration necrosis of cells of the glomerular layer in addition some hæmorrhage. In this section the "tubular ons" described by Rich (1944) can also be seen. The d cords of the cortex have been converted into tubes taining fibrinous exudate from the capillaries as ll as much cellular debris. Rich showed that the mary lesion in such cases was necrosis of the hormone- taining cortical cells, and that their death and orption allowed exudate from the capillaries to flow o the centre of the cortical cords, dissecting them for variable part of their length into "tubes." Such ons represent a gross interference with adrenal ction and may be present without hæmorrhage.

Another non-hæmorrhagic adrenal lesion is shown in . 10. This specimen is from a child of 5 years who died fulminating meningococcal septicæmia of adrenal pe nineteen hours after the appearance of the purpuric uption. It shows a band of fibrin 3 mm. thick rrounding the gland. This layer of fibrin covered the eater part of both glands. Sections of the suprarenal lands in this case showed only slight hæmorrhage but vere toxic changes in the cortical cells. The thick band of fibrin might have hindered absorption of hormonal secretion.

Such lesions may help to explain those cases which present the signs of fulminating septicæmia of adrenal type, including peripheral circulatory failure during life, but show no adrenal hæmorrhage after death. Absence of gross adrenal hæmorrhage has led some observers—e.g., Williams (1942)—to consider that undue importance has been ascribed to adrenal apoplexy as a cause of the circulatory collapse. It appears, however, that the non-hæmorrhagic microscopic lesions in the suprarenal glands may have been overlooked in some at least of these observations. Kinsman et al. (1946) demonstrated gross degenerative lesions in the cortical cells in 2 cases of this syndrome in which adrenal hæmorrhage was absent. They advanced the theory, based mainly on Rich's work, that the increased demand on the adrenal cells, as a result of the fulminating infection, depletes the cortical cells of lipoid or hormone-containing material. The cells degenerate rapidly, undergo lysis, and shrink, causing loss of support to the capillaries. Up to this point the damage may still be reversible, and efficient chemotherapy of the infection may save the patient. On the other hand, the patient may die from the functional damage or other factors before hæmorrhage takes place. In most fatal cases, however, the cortical capillaries rupture, owing to loss of support and possible weakening of their walls by toxic action. If the resulting hæmorrhage is gross it causes irreversible damage to the gland.

Fig. 10—Fulminating adrenal syndrome: periadrenal thick fibrinous exudate.

This theory seems to indicate at least one important cause of the circulatory failure in fatal cases of the adrenal syndrome in which hæmorrhage is not found, and also in recovered cases. It does not exclude the part played by toxic effects on many other organs and tissues—e.g., heart, vessels, and vasomotor mechanism; but it emphasises and explains the predominant part played by adrenal lesions. The latter include, in some cases, thrombosis of the large medullary venous sinuses along with gross hæmorrhage and necrosis, a condition which has been described as thrombotic necrosis. If the above theory is correct this term would merely describe the end-result and not necessarily the sequence of events, since the cortical necrosis might precede the thrombosis.

In my series all the fatal cases considered clinically to belong to this syndrome revealed hæmorrhagic or non-hæmorrhagic adrenal lesions which might be considered significant. Accordingly, without denying that the general vascular or other toxic lesions may play a part in the production of circulatory collapse, I consider that the correlation of symptoms with adrenal lesions is sufficiently striking to justify designation of this syndrome as "fulminating septicæmia of adrenal type," or, more briefly, "fulminating adrenal syndrome."

(3) *Mixed Encephalitic-adrenal Type*

In this syndrome early deep coma is combined with a purpuric rash and low blood-pressure. At necropsy both the brain and the suprarenals exhibit lesions of the kinds already described for fulminating septicæmia of encephalitic and of adrenal types. In my series there were 5 cases of the mixed syndrome, all fatal: 3 in infants and 2 in children aged 4 and 8 years.

distinguishes this disease from acute hæmorrhagic leucoencephalitis (Baker 1935) and other rare primary demyelinating diseases. Cases can easily be missed at necropsy if the brain and cord are not carefully examined histologically at all levels. I discovered, when I referred back to my pre-1939 cases, that, of 6 cases which clinically might have belonged to this syndrome, brain sections had been preserved only in 1, which on re-examination showed the typical lesion. Photomicrographs of brain sections of the 2 most protracted cases were shown in the original paper (Banks and McCartney 1942). Figs. 2, 3, and 4 show additional brain sections from 1 of these patients, a man of 22 who died on the fifth day of the disease after three days of deep coma. Fig. 5 is a section from another patient, a man of 24 who died on the fourth day of disease.

Though clinicopathological correlation seems fairly clear in such cases, it is naturally less clear in cases that are fatal within three days or less of the onset of the acute illness. I have examined 2 examples of this more acute type in a child of 2 and a man of 45 years. The man died after twenty-five hours' deep coma. The duration of the acute illness was not exactly determined but was probably about forty-eight hours or a little more. In this case sections of cortex, basal ganglia, mid-brain, and medulla all showed diffuse capillary thrombosis, with, here and there, slight perivascular round-celled infiltration limited to a single ring of cells (Banks and McCartney 1942). Fig. 6 is an additional section from this case and shows capillary thrombosis with slight round-cell perivascular infiltration. The lesions here are intermediate between those of the 2 more protracted cases referred to above and those of a fulminating encephalitic case to be described later.

Supporting evidence of the diffuse encephalitic basis of this syndrome is obtainable from recovered patients. In the original paper (Banks and McCartney 1942) we described the case of a girl of 15 with meningococcal meningitis who was in absolute coma for three days and then slowly emerged, becoming rational, but with very slow cerebration, after five days' intensive sulphonamide treatment. During early convalescence she had a mask-like expression, which lasted three weeks. She also had an upper-neurone facial paresis as well as a lower-neurone bilateral sixth-nerve paralysis. The combination of protracted deep coma, transient parkinsonism in convalescence, and upper-neurone involvement, when considered with the pathological data already demonstrated, more than suggests a widespread parenchymatous lesion in the central nervous system.

FULMINATING MENINGOCOCCAL SEPTICÆMIA

Meningococcal septicæmia is sometimes overwhelming and fatal in from as little as four hours from onset to forty-eight hours. Meningitis in such cases is a relatively negligible factor; it is usually absent or just beginning before death or recovery.

It is an old observation that a broad distinction can be drawn clinically between two kinds of fulminating meningococcal septicæmia: that in which the brunt of the onslaught is on the central nervous system, and that in which it is on the peripheral circulation. We have tried to demonstrate a correlation of the first type with the lesions in the brain, minimal as they must be in such a rapidly fatal infection, and of the second type with lesions in the suprarenal glands. We found, however, in a considerable proportion of cases, that both of these systems were involved, giving rise to a mixed clinical syndrome which is confusing, and has actually been confused in the so-called Waterhouse-Friderichsen syndrome (Banks and McCartney 1943).

There are other sources of confusion too in this medley of fulminating meningococcal septicæmia. There is evidence that the pituitary gland is occasionally involved (see below). Again, Morison (1943), on the basis of necropsies on 3 cases with adrenal hæmorrhage, thought that the evidence favoured a generalised vascular lesion leading to peripheral circulatory failure or shock symptoms by the usual mechanism of plasma loss from the circulation. He and others—e.g., Williams (1942)—consider that the lesions in the suprarenals play a relatively insignificant part compared with the genera toxic lesions in the production of the symptoms of peripheral circulatory failure. Against this view, however must be placed many observations indicating that the shock of severe acute infections has a different origi from that associated with trauma or hæmorrhage. Ebert and Stead (1941), for example, showed that the peripheral circulatory failure in 8 cases of severe acute infections was not associated with a decrease in the volume of the plasma or with any other laboratory test of hæmoconcentration. Moreover, it was not altered by transfusion of plasma or blood. To my knowledge hæmoconcentration has not actually been demonstrated during life in fulminating meningococcal septicæmia. shall return to this point again; meanwhile I suggest that sufficient correlation between organic damage and clinical symptoms has been demonstrated to justify th classification of fulminating meningococcal septicæmi into three broad types: (1) encephalitic; (2) ad (this might be understood to include occasional pituitary lesions); and (3) mixed or encephalitic-adrenal. Such classification has at least the advantage of suggesting treatment appropriate to the type.

I deprecate the use of the term "Waterhouse-Friderichsen syndrome" for cases of fulminating septicæmia with massive purpura and bilateral adren hæmorrhage, because this syndrome seems to be composite affair which includes both the "pure adrenal" and the "mixed" syndromes, and so leads to confusion of symptomatology and of treatment. I think it particularly important to distinguish between cases which the patients are comatose from an early stage and those in which they are mentally clear. This is not done in the Waterhouse-Friderichsen syndrome, but it is cardinal distinction in our classification.

(1) *Encephalitic Type*

This is represented by 6 cases in my series of 706 cases of meningococcal disease: 2 in infants, 2 in children o 3 years, and 2 in young adults. All were fatal within forty-eight hours of onset. All of them were acute medical emergencies. Onset was sudden, with anorexia vomiting, and fever. Lethargy, stupor, and then absolute coma rapidly developed, accompanied by laboured a stertorous breathing. A petechial but not massive purpuric rash appeared within about 12–18 hours o onset, and meningococci were found in the blood. I infants convulsions occurred. The plantar reflexes were extensor. Blood-pressure was normal.

At necropsy the brain was grossly congested and œdematous, and sometimes as much as 50% overweight Sections at various levels showed early purulent meningitis, and in the parenchyma diffuse capillary thrombosis small hæmorrhages, and some degeneration of neurone cells. No adrenal or other conspicuous lesion was apparent.

Banks and McCartney (1942) published brain sections from an infant of 11 months who died after thirty-six hours' illness, including ten hours' complete coma These showed capillary thrombosis, slight perivascular infiltration, and capillary hæmorrhages. Fig. 7 is another section from the same case, showing capillary thrombosis and slight perivascular infiltration. The lesions, as would be expected, are minimal but may be interpreted as a very acute encephalitic basis for the deep coma which is the cardinal sign of fulminating meningococcal septicæmia of the encephalitic type.

INFECTION BY PENICILLIN-RESISTANT STAPHYLOCOCCI

MARY BARBER
M.D. Lond.

MARY ROZWADOWSKA-DOWZENKO
M.D. Warsaw

the Bacteriology Department, Postgraduate Medical School of London

ANY studies have been carried out on the incidence penicillin-resistant strains of *Staph. pyogenes* in cases nfection. Until 1944 few such strains were encountered. e then, however, the incidence has been increasing idly, particularly in hospitals. Studies in which e than 10% of all strains tested were found to be stant to penicillin have been recorded by Spink et al. 44), Bondi and Dietz (1945), Gallardo (1945), Plough 45), Harley et al. (1946), Barber (1947a and b), and pson (1947). In a previous report one of us (Barber 7b) showed that in less than a year the incidence penicillin-resistant strains of *Staph. pyogenes* giving to infection in this hospital had gone up from 14·1 38%. The work reported here shows that this rease is continuing.

All pus swabs received in the laboratory during this estigation have been plated directly on to plain blood-agar es and penicillin-ditch plates, the ditch containing 10 units penicillin per ml. of agar. If other specimens from cases fection yielded a heavy growth of *Staph. pyogenes*, this th was emulsified in broth and replated on a penicillin- h plate. All staphylococci were tested for coagulase, only those which were positive were included in the series. ny coagulase-positive staphylococci were shown on the h plate to be resistant to penicillin, colonies, usually ten, e picked from a plain blood-agar plate and tested indi- ally for penicillin resistance. All resistant strains isolated e tested for their capacity to destroy penicillin by the hod used in the previous studies (Barber 1947a). Sensi- ty to streptomycin was tested on ditch plates, the ditch aining 100 units of streptomycin per ml. of agar. Part every ditch plate used, whether for testing streptomycin penicillin sensitivity, was seeded with the Oxford phylococcus as a control.

LE I—ANALYSIS OF PATIENTS YIELDING *Staph. pyogenes*

Series	Total patients	Patients with penicillin-resistant strains		
		Total	All colonies tested resistant	Sensitive and resistant colonies isolated
I vember,	99	14 (*14·1%*)	9 (*9·1%*)	5 (*5·1%*
II ry-June,)	100	38	30	8
III ary-June,)	100	59	39	20

ANALYSIS OF RESISTANT STRAINS

Specimens from 100 patients with staphylococcal fection were examined. From 59 patients penicillin- istant strains of *Staph. pyogenes* were isolated; from 9 all colonies tested were resistant, and from 20 both sistant and sensitive strains were isolated. These ults are compared in table I with those of the two evious studies. It will be seen that the incidence of atients yielding penicillin-resistant strains has risen rom 14·1% in 1946 to 38% in 1947 and 59% in 1948. n the present series 20 patients gave mixed cultures of enicillin-sensitive and penicillin-resistant strains. In 17 of these patients the mixture was present in a single specimen, and 8 gave only a few penicillin-resistant colonies. From 3 the first specimen received yielded only penicillin-sensitive staphylococci, but from later specimens penicillin-resistant strains were isolated. These 3 patients will be referred to again in connexion with the source of resistant strains. The results according to type of infection were as follows:

Type of infection	*Total patients*	*Patients yielding penicillin-resistant strains*
Septicæmia	2	2
Boils, abscesses, &c.	23	8
Superficial skin lesions	12	8
Infected operation wounds	12	10
Pulmonary	10	7
Conjunctivitis	22	11
Aural	5	3
Nasopharyngeal	6	5
Umbilical of newborn	3	3
Urinary	3	1
Vaginal	2	1
Total	100	59

The 2 patients with septicæmia both died, in spite of intensive penicillin treatment.

One was a newborn infant in whom the infection appeared to enter via the umbilical cord. The infant had had no penicillin before the infection.

The other was a patient with bilateral cortical necrosis of both kidneys following toxæmia of pregnancy and treated with the artificial kidney. Penicillin treatment was started when the patient was put on the artificial kidney, and maintained after the development of septicæmia. Owing to the kidney deficiency a very high blood-penicillin level was reached, but the infecting staphylococcus was so resistant that it was isolated from a blood-culture while the patient was on a dose of penicillin giving levels up to 8 units per ml. of serum. Though the condition of the kidneys would probably have caused death eventually, necropsy revealed septic thrombosis of one iliac vein and the inferior vena cava, septic infarcts throughout both lungs, and one small abscess in the myocardium.

The cases of abscess were of all grades of severity, and the abscesses were in various sites. The superficial skin lesions consisted of ulcers, gangrene, bedsores, burns, dermatitis, and septic spots. The lung infections included pneumonia, bronchiectasis, lung abscess, and tuberculosis. Of the 22 cases of conjunctivitis 20 were neonatal. Of the 5 patients with aural infection, 4 were children with otitis media, and 1 was an adult diabetic with external otitis.

In view of Voureka's (1948) claim that penicillin-resistant staphylococci can be rendered sensitive by growth in the presence of other organisms, whether the latter are sensitive or resistant to penicillin, the strains in this study have been analysed according to whether they were isolated in pure or in mixed culture. The results (table II) show that 34 of the 59 penicillin-resistant strains were originally isolated from 48 mixed cultures, whereas only 25 penicillin-resistant strains were isolated from 52 pure cultures. The large proportion of penicillin-resistant staphylococci isolated from cultures yielding other penicillin-resistant organisms is interesting, but the figures here are too small to be statistically significant.

TABLE II—ASSOCIATION OF *Staph. pyogenes* WITH OTHER ORGANISMS

—	No. of pure cultures	No. of mixed cultures		
		Total	Other bacteria penicillin-sensitive	Some or all other bacteria penicillin-resistant
Total	52	48	27	21
No. yielding penicillin-resistant strains of *Staph. pyogenes*	25 (*48%*)	34 (*71%*)	18	16

Total	706	654	52

Occasionally, the pituitary gland may be damaged, as in a fatal case clinically corresponding to the mixed syndrome and showing three areas of coagulation necrosis in the pituitary (Gordon and Shimkin 1943). One of my recovered cases of the adrenal type, a child of normal development at the age of 6 years at the time of the illness (Banks and McCartney 1943), was found at the age of 12 to be suffering from the pituitary form of dwarfism. She had grown only 2 inches in the intervening six years and the ossification of certain epiphyses was delayed.

ACUTE FOCAL ENCEPHALITIC SYNDROME

There still remain some fatal cases of meningococcal disease which do not quite fit into any of the above categories. All workers at this subject have been puzzled, at some necropsies, about the precise cause of death. This was expressed by Thomas (1943) in his description of U.S. Army experiences during the war:

> “Out of 46 cases coming to autopsy 18 had gross adrenal hæmorrhage and in most of the remaining cases the cause of death was not clear. The meningitis was cured or subsiding, and death could only be ascribed to toxic action or increased intracranial pressure.”

Some of these puzzling cases appear to belong at first to the severe ordinary form, and after a day or two they show signs of recovery. This phase, however, is succeeded by sudden or unexpected collapse, convulsions, or coma and death. In some such cases Banks and McCartney (1942) found focal vascular lesions in the brain stem and the cervical cord. The lesions consisted of isolated focal hæmorrhages, hyaline capillary thrombi, swollen capillary endothelium, and slight perivascular infiltration. Often there was also chromatolysis of nerve-cells. In one case the focal lesion had produced a large subdural hæmorrhage. In some cases these lesions were situated close to the vital medullary centres.

We tentatively suggested that such focal encephalitic lesions might explain some of these unexpected tragedies in which the purulent meningitis had practically subsided at the time of death and could not in itself have caused death. Careful histological examination of necropsy material is necessary for the discovery of most of these focal lesions. There were 6 cases in my series, all fatal—1 infant, 1 child, and 2 young and 2 middle-aged adults. Clinical particulars and brain sections of 2 cases showing focal hæmorrhages have been described (Banks and McCartney 1942). Fig. 9 is a section of the mid-brain from the case of subdural hæmorrhage mentioned above. It shows one large focal hæmorrhage and several smaller ones. Another case in the series was a man of 42 who died on the twelfth day of disease after two successive large cerebral hæmorrhages within twenty-four hours, involving each internal capsule. Up to the ninth day of the dise he had appeared to be a case of the ordinary form.

MILD AND ABORTIVE FORMS

Many cases of mild clinical and subclinical infect undoubtedly occur during an epidemic, especially at tail end of it. The symptoms include mild pyre headache, stiffness of neck and back, and in abort cases they may disappear in a day or two without spec treatment. Other mild cases, however, do not c spontaneously, and the diagnosis may be missed fo week or two, until increasing headache, or contin fretfulness in an infant, compels investigation by lum puncture. Such cases may be extremely dangerous ow to slow formation of arachnoid adhesions, with product of hydrocephalus, subarachnoid block, and someth compression paraplegia.

CHRONIC FORM

The chronic form is a development of the ordin form, generally when the latter has been unrecogni or untreated in the early acute stage. It is referre below. In my series of 706 cases 10 patients had chronic form, of whom 5 died. This form is now m rarer than it was in the presulphonamide days.

MISCELLANEOUS FORMS

Other rare forms of meningococcosis include prim meningococcal ophthalmia, meningococcal hepatitis, meningococcal pneumonia. Some 30 cases of the have been reported, the majority in males so far a known, under the age of 25 years. It is a prim purulent conjunctivitis involving one or both e Corneal ulceration was noted in about a sixth of cases. In about a third there was a history of throat. In no case was the eye permanently dama Meningitis followed in 1 case, and meningoco septicæmia in 2 (Shuttleworth and Benstead 1947).

A case of meningococcal jaundice was reported Crawford (1944) in which jaundice appeared twenty- hours after the onset of a febrile illness and continued ten days concurrently with meningococcal septicæm before it was diagnosed by blood-culture and trea with sulphonamides; the temperature then fell normal in twenty-four hours, and the jaundice appeared a day later. This case closely resembled W disease, but tests for this were all negative.

A considerable number of cases of meningococ pneumonia were reported in the first world war association with the great influenza pandemic (H and Davison 1919). In the second world war only case was reported (Roberg 1945). Subsequently B (1948) reported two cases, one of which was complica by meningococcal empyema. In all these the menin coccus was cultured from the blood or the lung or sputum, and it was not present in the cerebrospinal fl

Table II summarises the varieties of meningococc observed in my hospital series of 706 cases and gi their incidence and fatality rates.

(To be concluded)

“ . . . no matter how great the effort, many epileptics w sooner or later, fail in life's struggle—failure due not to fau of their own but to public ignorance. The enlightenment public opinion is a tough job. A strong national organisati with a whole-time staff and adequate funds, could do mu to change public opinion; *such an organisation would ser the needs of the epileptic in the same way and with the sa force* as the National Institute for the Blind acts for the blin the National Institute for the Deaf for the deaf, and t Diabetic Association for the diabetic. . . . Granted good medi care and a strong national organisation there still remains f epileptics the greatest need of all—regular work.”—*Dr.* P HENDERSON, addressing the Royal Institute of Public Heal and Hygiene on Oct. 20.

the presence of similar organisms. The results are given in table III.

Penicillin-resistant strains of *Staph. pyogenes* were isolated from 2 surgeons and 4 nurses; from 4 of the 6 all colonies of *Staph. pyogenes* isolated appeared to be penicillin-resistant, and from 2 resistant and sensitive colonies were isolated. Penicillin-resistant colonies from all these 6 members of the staff, from the 9 cases of operation wounds infected with penicillin-resistant strains of *Staph. pyogenes*, and from one patient with a similarly infected burn were phage typed as follows:

Source		*Date of isolation*		*Phage reaction*
Infected wound 1	...	March 3	..	47 (+)
„ „ 2	..	Feb. 23	..	47 (+)
„ „ 3	..	„ 26	..	47 (+)
„ „ 4	..	March 3	..	47 (+)
„ „ 5	..	April 12	..	6/47 (+)
„ „ 6	..	„ 20	..	47 (+)
„ „ 7	..	„ 19	..	47 (+)
„ „ 8	..	„ 19	..	47 (+)
„ „ 9	..	May 7	..	47 (+)
„ burn ..	..	April 27	..	6/47 (+)
Surgeon 1 Skin	..	March 31	..	6/47 (+)
„ 2 Nose	..	April 24	..	3B/3C/51
Nurse 1 Nose ..	..	March 31	..	N.T.
„ 2 „ ..	..	April 3	..	42B/42E/47C
„ 3 „ ..	..	March 31	..	N.T.
„ 4 „ ..	..	„ 31	..	47 (+)

(+) = side reactions. N.T. = not typable.

It will be seen that 8 of the 10 patients were infected by staphylococci of the same phage type, 47 (+), and that one nurse carried this type in her nose. The strains from the other 2 patients were both 6/47 (+), and this phage type was present on the skin of one surgeon. What, however, is rather surprising is that at least 3 other penicillin-resistant phage types were present in the noses of members of the staff.

Previously it had been found (Barber 1947b) that the proportion of penicillin-resistant staphylococci in the maternity department was 56% while that of the rest of the hospital was 38%. It had also been shown that 5 infections with such strains in this department in six weeks were all due to organisms of phage type 6/47. It had been shown that *Staph. pyogenes* of this phage type was present in the air of 2 of the maternity wards at about the same time. Since then precautions had been taken in this department to guard against cross-infection, and all prophylactic penicillin had been stopped. In the present series 31 cases came from maternity wards, and 17 (55%) of them were due to penicillin-resistant organisms.

DISCUSSION

Three important questions arise in connexion with these penicillin-resistant strains of *Staph. pyogenes*, and at present no satisfactory answer can be given to any of them.

1. How do these strains arise? Before attempting to deal with the more fundamental aspect of this question I think it should be stated that, though penicillin-resistant strains of *Staph. pyogenes* are now appearing with increasing frequency in many hospitals, this is probably not the case in the community at large. Harley et al. (1946) showed that the percentage incidence of penicillin-resistant strains of *Staph. pyogenes* as hospital infections in wounds was nearly double that of the percentage in all infections. This would be expected. The frequency of cross-infection in hospitals has been emphasised by many workers (see Miles et al. 1940, Allison et al. 1946). Gillespie et al. (1939) showed that up to 40% of the hospital staff might carry *Staph. pyogenes*, and this has since been confirmed repeatedly. That these human carriers often give rise to hospital infections is not now disputed, and they, together with cross-infection from patient to patient, are probably the ultimate cause of all such cases (Hare and Mackenzie 1946). It is equally possible that a member of the staff may become a nasal carrier of a particular strain of staphylococcus as a result of infection from a patient. Thus it is possible that the number of strains of staphylococci in infections in a particular hospital at any one time may be quite small, and once a penicillin-resistant strain appears it will survive while penicillin-sensitive strains are rapidly eliminated by penicillin. Thus by a simple process of selection penicillin-resistant staphylococci may come to outnumber penicillin-sensitive strains. That this process of selection is taking place is clear from the phage reactions listed above, and from the fact that a similar group of infections in one department in the 1947 series were all caused by penicillin-resistant staphylococci of the same phage type.

Is this process of selection the whole story? Or are these penicillin-resistant strains organisms which were naturally sensitive to penicillin but at some stage in their career acquired resistance to it? The former hypothesis is supported by cases 2 and 3, who yielded penicillin-sensitive and penicillin-resistant strains of unrelated phage types. A similar case was reported in the series studied between February and June, 1947 (Barber 1947b), and 5 such cases in the series of April-November, 1946 (Barber 1947a). On the other hand, case 4 of the present series and a patient in the 1946 series had penicillin-sensitive and penicillin-resistant organisms of the same phage type, and North and Christie (1946) have reported a case where a single serological type of *Staph. pyogenes* appeared to develop resistance under treatment.

One objection to the view that these strains acquire their resistance is that it has not so far been possible to train a staphylococcus in vitro to destroy penicillin. The type of resistance to penicillin produced in the test-tube is quite different. Whether or not, however, these penicillinase-producing staphylococci acquire their resistance, as indicated above selection probably plays a large part in the increasing frequency of their appearance.

2. Can infections with these organisms be successfully combated with massive doses of penicillin? It appears that they can in some cases. The determining factor is probably the heaviness of the infection. These staphylococci are resistant to penicillin largely because they destroy it; a large inoculum has enough ready-made penicillinase to grow in 1000 units of penicillin per ml., whereas a small inoculum may be inhibited by less than 1 unit per ml.

3. Is it possible to make these resistant organisms sensitive to penicillin? Both Voureka (1948) and Winner (1948) claim that this can be done by growing them in mixed cultures. We have been unable to confirm this. I have pointed out (Barber 1948) that strains which have been kept in the laboratory for some time do not breed true but tend to give rise to increasing numbers of penicillin-sensitive daughter colonies; and that after growing ten strains in the presence of the Milne streptococcus, which was one of the organisms used by Voureka, there was no significant increase in the number of penicillin-sensitive colonies. Voureka (1948) started her work with the suggestion that penicillin-resistant organisms might lack some chemical factor which other bacteria might supply, thus rendering the resistant organisms sensitive to penicillin. She does not differentiate clearly in her paper between staphylococci which have acquired resistance in vitro and penicillinase-producing strains. Whatever may be the case with the former, it seems clear that the latter do not lack anything but, on the contrary, have an extra property—the capacity to destroy penicillin. They show none of the morphological, cultural, and pathogenic differences seen in staphylococci which have acquired resistance in vitro. Voureka's claim that the same process renders both types of resistant organism sensitive seems unlikely. However, since penicillinase-producing staphylococci do not breed true, it seems possible that the

DEGREE AND TYPE OF RESISTANCE

All the 59 resistant strains produced penicillinase. As has been shown previously (Luria 1946, Barber 1947a), the degree of resistance of such strains when measured in the laboratory may vary many hundredfold according to the size of inoculum used. Therefore no attempt has been made in this study to estimate the exact amount of penicillin which would inhibit growth. It may be said, however, of all the strains that if a single colony was streaked across a penicillin-ditch plate containing 10 units of penicillin per ml. of agar in the ditch, growth took place right across the plate. Strains showing a minor degree of resistance were not encountered. One interesting phenomenon shown by these penicillin-destroying staphylococci was that colonies in the neighbourhood of the ditch were just as large as those elsewhere. Where the inoculum was small, growth of such organisms might be completely inhibited by the penicillin in the ditch; but if growth did take place it was apparently unimpeded. This is in striking contrast to the growth of a *penicillin-sensitive staphylococcus*, which usually shows progressively smaller colonies as the ditch is approached.

STREPTOMYCIN SENSITIVITY

Streptomycin-sensitivity was tested in 97 strains: 55 were penicillin-resistant; 13 were penicillin-sensitive strains isolated in association with 13 of the resistant cultures; and 29 were penicillin-sensitive strains isolated from patients who yielded no penicillin-resistant colonies. Broth-cultures of the organism were plated on to streptomycin-ditch plates opposite a culture of the Oxford staphylococcus. All 42 penicillin-sensitive and 53 of the 55 penicillin-resistant strains showed a sensitivity to streptomycin similar to that of the Oxford staphylococcus; one penicillin-resistant strain showed a few resistant colonies when the broth-culture was plated on a streptomycin-ditch plate, but 50 colonies picked from a plain blood-agar plate and streaked across a streptomycin-ditch plate all showed a sensitivity similar to that of the Oxford staphylococcus; from one penicillin-resistant strain all colonies tested appeared to be considerably more resistant than the Oxford staphylococcus to streptomycin.

SOURCE OF RESISTANT STRAINS

It is not disputed that the rapid increase of penicillin-resistant staphylococci is primarily caused by the widespread use of penicillin. There are, however, at least two ways in which penicillin may have this effect. Either a strain may acquire resistance to penicillin, or naturally resistant organisms, originally few, may survive while penicillin-sensitive organisms are destroyed, and thus by a simple process of selection become increasingly common. In an attempt to find out whether one or both of these processes is taking place, the results here recorded have been studied in relation to penicillin treatment and epidemiology. Selected groups of staphylococci were kindly phage typed by Dr. Allison.

The penicillin sensitivity of *Staph. pyogenes* in relation to previous recent treatment with penicillin was as follows:

	Penicillin	*No penicillin*
Penicillin-sensitive strains only ..	4	37
Penicillin-resistant strains isolated	29	30

Only 4 patients who had had penicillin before the swab was taken yielded penicillin-sensitive staphylococci, and 2 of these 4 had only been treated for a day, and 1 only for two days. On the other hand, 30 patients who had not had penicillin recently before the swab was taken yielded penicillin-resistant strains. Of these 30 patients 1 had had a course of penicillin injections three months previously, but no history of penicillin treatment at any time was obtained from the remaining 29. It is interesting, however, that 21 of this group of patien were in the maternity department, 19 having neonat infections.

As stated previously, from 3 patients (cases 1, 2, and the first specimens tested yielded staphylococci whi were all as sensitive as the Oxford staphylococcus penicillin, but subsequent specimens revealed the presen of penicillin-resistant staphylococci.

Case 1 had empyema, and the first specimen of pus examin was taken after a three-week course of penicillin injectio (30,000 units three-hourly). This gave a growth of penicilli- resistant *Ps. pyocyanea* and penicillin-sensitive *Staph. pyogen* Three weeks later a second specimen yielded *Proteus, I pyocyanea*, and a few colonies of *Staph. pyogenes*, all of whi were penicillin-resistant.

Case 2 had an abscess in each axilla. A specimen of p from the right axilla, taken on March 8, gave a pure grow of *Staph. pyogenes*, all of which appeared as sensitive as t Oxford staphylococcus to penicillin. Penicillin treatmen 60,000 units six-hourly, was started, and specimens of p taken next day from both axillæ yielded pure growths *Staph. pyogenes*, but the specimen from the right axi showed a few penicillin-resistant colonies. A penicill sensitive colony from each of the three specimens and one the penicillin-resistant colonies were all subcultured and se to Dr. Allison for phage typing. The phage reactions w as follows:

Source of specimen		*Date of specimen*		*Penicillin-sensitive colonies*		*Penicillin-resistant colonies*
Right axilla ..		March 8	..	42 E	..	—
,, ,, ..		,, 9	..	42 E	..	6/47
Left ,, ..		,, 9	..	42 E	..	—

It will be seen that the three penicillin-sensitive coloni were of the same phage type, whereas the resistant colo- was different.

Case 3 had bronchopneumonia and bronchiectasis I sputum on admission gave a pure growth of penicilli sensitive *Staph. pyogenes*. Four days later, after 24 hou penicillin treatment (30,000 units three-hourly), a seco specimen gave a similar pure growth of *Staph. pyogenes*, b of 20 colonies tested against penicillin 19 were resistant a 1 was as sensitive as the Oxford staphylococcus. Sensitiv and resistant colonies were phage typed as follows:

Date of specimen				*Penicillin-sensitive colonies*			*Penicillin-resistant colonies*
7/5	..	..	..	52	..	..	—
11/5	..	..	..	44A (w)		..	47 (+)

(w) = weak. (+) = side reactions.

Here it is seen that all 3 colonies tested were of differen phage types.

Case 4, in contrast to cases 2 and 3, had an infected oper tion wound which gave a mixed flora of *Proteus* and *Stap pyogenes*; 10 of the staphylococcal colonies from this cas were tested against penicillin, and 9 were found resistant an 1 sensitive. A sensitive and a resistant colony were phag typed, and both gave the reaction *47 (+)*.

Of the patients studied, 17 came from the two main surgical wards, and 13 of these yielded penicillin-resistan strains of *Staph. pyogenes*. In 10 of the patients the organisms were isolated from infected operation wounds, and from 9 of these 10 patients *penicillin-resistant* strain were isolated. The noses and skin of 21 members of the staff working in these wards were therefore tested for

ing and Smith (1939) described one case in a man of , in which improvement did not follow bilateral denervation; however, few details are given and, though they state that both sinuses were hypersensitive, they do not mention whether the attacks could be reproduced by pressure over them.

ANATOMY OF NERVES OF CAROTID SINUS

The nerves of the carotid sinus are disposed in three groups or pedicles, derived from the glossopharyngeal nerve, the vagus nerve, and sympathetic nerves (fig 1).

(1) *From the Glossopharyngeal Nerve.*—At the point where the glossopharyngeal nerve crosses the lateral aspect of the internal carotid artery it gives off two branches which descend on the lateral aspect of the artery, pass towards its anterior aspect, and end in the anterior border of the carotid body.

(2) *From the Vagus Nerve.*—The vagus nerve supplies a lateral and a medial set of branches. The lateral branches arise from the trunk of the nerve or from the ganglion nodosum. They follow the same course as the glossopharyngeal pedicle, with which they are intimately related. The medial (and more important) branches first run with the superior laryngeal and pharyngeal branches of the vagus; leaving these, they pass to the posterior aspect of the internal carotid artery to end in the posterior border of the carotid body.

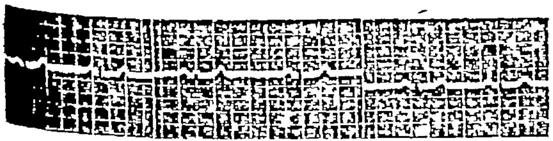

Fig. 4—Electrocardiogram.

(3) *From Sympathetic Nerves.*—Numerous fibres spring from the superior cervical ganglion and the pharyngeal plexus, run in contact with the posterior aspect of the internal carotid artery, and end (above the nerves of the vagal pedicle) in the posterior border of the carotid body. Occasionally a twig reaches the carotid body from the hypoglossal nerve

CASE-RECORD

The following is an example of the vagal type, apparently cured by bilateral carotid-sinus denervation, without any adverse after effects.

A retired banker, aged 61, was admitted as an emergency on Dec. 10, 1946, after a sudden attack of giddiness and vomiting.

Past History.—About 15 years ago, while sitting at his office desk, he had an attack of weakness in which his head fell back suddenly two or three times, for no accountable reason, and he was off work for several weeks. For the past 12 years or so, he had had "giddy turns," consisting of the sudden onset of a sensation of falling to one side or the other, with a swaying or staggering gait. The first attack came on while he was playing golf; other attacks have occurred when turning quickly, looking up—e.g., at a bookshelf—moving his head to one side or the other, and sometimes while sitting still at his desk. There is no warning of an attack, and he has never lost consciousness. The attacks have gradually become more frequent but are usually of a similar severity and last about 10 minutes. Once he wanted to get out of bed in the night and, turning on his left elbow, fell suddenly and violently backwards. This happened five or six times until he felt faint and sick.

He has been under the care of his doctor, who has called about once a month, and records of the blood-pressure have been kept: from December, 1945, the readings have been 160–200/110–115 mm. Hg.

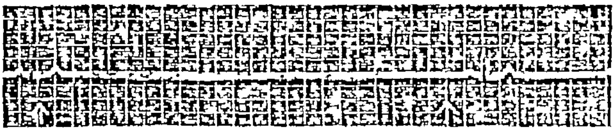

Fig. 5—Cardiac asystole caused by pressure over right carotid sinus: *a*, pressure applied; *b*, pressure released.

The patient has occasionally noted "blind spots," usually associated with his attacks but sometimes not, consisting of a black area about 10 cm. wide, outlined by a quivering margin, on the page which he is reading. Apart from minor disorders, he has otherwise been well; but he had a nervous breakdown in 1914, benign "glycosuria" in 1925, and his doctor has always thought some of his symptoms were of nervous origin. The patient recently retired from business. A labyrinthine cause for the attacks has been excluded.

Family History.—His father was an asthmatic and died of Bright's disease at 66. His mother died at his birth.

Present Illness.—On the day of admission the patient experienced temporary giddiness when he got out of a tram-car and turned suddenly to cross the road. He went into a restaurant and began his lunch. Again he felt sick, with sweating and water-brash, got up, and staggered to the cloakroom, where he was violently sick and collapsed.

On Admission.—General condition good. High-coloured with clinical polycythæmia. Still feeling cold after his attack but well oriented and not collapsed. Heart not clinically enlarged. No abnormality on auscultation. Blood-pressure 220/130 mm. Hg; with a silent gap between 210 and 160 mm. Pulse regular, rate 80 per min.; mild retinal arteriosclerosis. Other systems normal.

Radiography.—Left ventricle not enlarged. Cardiac outline normal. No hilar congestion. Aorta somewhat uncoiled, elongated, and dense, suggesting atheroma (figs. 2 and 3).

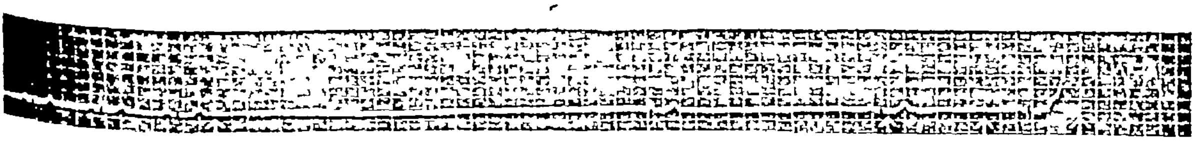

Fig. 6—Effect of pressure over left carotid sinus: *a*, pressure applied; *b*, loss of consciousness; *c*, convulsion; *d*, pressure released.

natural tendency of the organisms to produce penicillin-sensitive daughter colonies might be accelerated by artificial means. Further research along these lines is clearly needed.

SUMMARY

Of 100 cases of infection with *Staph. pyogenes* investigated in one hospital between April and June, 1948, 59 yielded penicillin-resistant organisms. Previous studies in the same hospital gave an incidence of 14·1% in 1946 and 38% in 1947.

The 59 resistant strains have been analysed according to type of infection and whether they were isolated in pure or mixed culture.

All 59 produced penicillinase and when tested by streaking a single colony across a penicillin-ditch plate were resistant to at least 10 units of penicillin per ml.

The incidence of resistant strains has been studied in relation to penicillin treatment and epidemiology in an attempt to throw light on their source. It is suggested that a process of selection is the major factor for their increasing incidence in hospitals.

Our thanks are due to Dr. V. D. Allison for the phage typing results and to Dr. E. Cooper, Dr. J. Holborow, and Dr. D. Mitchison for the primary isolation of many of the strains.

CAROTID-SINUS SYNDROME

A CASE TREATED BY BILATERAL DENERVATION

RICHARD TURNER
O.B.E., M.D. Camb., M.R.C.P.

REGIUS PROFESSOR OF CLINICAL SURGERY AND PROFESSOR OF SURGERY

UNIVERSITY OF EDINBURGH

From the Western General Hospital and the Royal Infirmary, Edinburgh

Hering (1927) discovered the mechanism in animals through which pressure over the carotid sinus leads to slowing of the heart, by demonstrating sensory nerve-endings in the wall of the artery and tracing afferent nervous connexions with the medulla. These observations were confirmed by Heymans (1929) and later workers. It is now established that afferent impulses, arising as a result of stimulation of receptor organs in the adventitia of the carotid sinus and aortic arch by changes in intra-arterial pressure, normally play a part in the reflex regulation of blood-pressure and heart-rate; the centre for the reflex is in the medulla. An increase in intracarotid pressure is followed by a reduction in the systemic blood-pressure and in the heart-rate; a decrease has the opposite effect. The reflex is most active when the change in intracarotid pressure is sudden. It is present in man, and most marked in hypertensive persons.

The clinical implications of these observations studied in detail by Weiss and Baker (1933), Ferris et (1935), and Weiss et al. (1936), who showed that sensitivity of the carotid-sinus reflex might be resp for some cases of syncope and of convulsions, and lesser disorders of cerebral function as dizziness weakness. The patient is usually a middle-aged elderly man, often with arteriosclerosis, hypertensio and emotional instability. Symptoms may be precipitat by a sudden movement of the neck, may appear warning, or may be preceded by an aura such as wea ness, dizziness, or epigastric discomfort. At the of an attack the patient is usually standing or and further symptoms, such as loss of consci may be prevented by lying down immediately.

Three types of attack were described, depending the dominant motor pathway of the hypersensitive reflex:

(1) *Vagal.*—Cardiac arrest from sino-auricular or auriculo-ventricular block, leading to cerebral anoxæmia and a fall in blood-pressure. This can be abolished with atropine and prevented with adrenaline through its local stimulating effect on the ventricules.

(2) *Depressor.*—Reflex vasodilatation with a fall in blood-pressure and cerebral anoxæmia, the least common type. This can be aborted or prevented with adrenaline but not abolished with atropine.

(3) *Cerebral.*—No change in heart-rate or blood-pressure, but stimulation of cerebral centres as a result of impulses reaching the medulla. This is not affected either by atropine or by adrenaline.

Mixed forms may occur. Naturally such attacks cause nervousness and anxiety. The important diagnos point which distinguishes them from other conditions, such as epilepsy, is their constant reproduction b pressure over one or other carotid sinus.

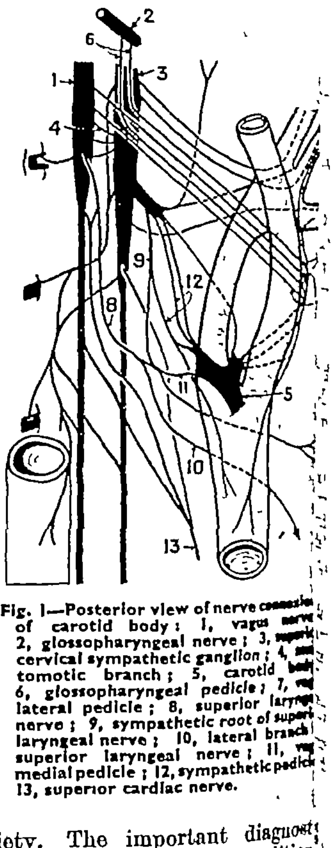

Fig. 1—Posterior view of nerve of carotid body: 1, vagus 2, glossopharyngeal nerve; 3, cervical sympathetic ganglion; 4, tomotic branch; 5, carotid 6, glossopharyngeal pedicle; 7, lateral pedicle; 8, superior laryn nerve; 9, sympathetic root of super laryngeal nerve; 10, lateral branch superior laryngeal nerve; 11, medial pedicle; 12, sympathetic pedic 13, superior cardiac nerve.

If the attacks are mild and not seriously incapacitatin reassurance, and the administration of sedatives an ephedrine may be all that is necessary; but, if they a severe and recurrent and there is no response to simpl measures, denervation of the carotid sinus on one or bot sides is indicated, a procedure shown by Weiss et (1936) to abolish the reflex. Examples of successf unilateral denervation have been reported.

It has been shown that unilateral carotid-sinu denervation has no permanent ill effects (Craig an Smith 1939, Mulholland and Rovenstine 1941, Ray an Stewart 1942), but reports on bilateral denervation ar few, at least in English publications, and this operatio seems seldom to have been performed, presuma through fear of untoward after effects. Capps and Takats (1938) re-investigated two patients on whom t procedure had been carried out apparently for epilep and found that neither hypertension nor tachyca had resulted; but postural hypotension was considerable polymorphs 39%, eosinophils 2%, lymphocytes 53%, monocytes 3%). The mother's Wassermann reaction was negative. Glucose water by mouth was advised, and the diarrhœa and vomiting ceased. However, by this time the mother's breast-milk had failed, so bottle-feeding was started.

A right otorrhœa developed 18 days later, and in a further 2 days the vomiting recommenced; on the following day everything by mouth was returned and there was mucus in the vomits. When taken to hospital the next day only boiled water by mouth for 24 hours was prescribed. The vomiting ceased before the 24 hours were up, so the mother again resumed milk feeds; and there was further vomiting. For the ensuing 2 days glucose water only was given by mouth, and the child was then sent to this hospital.

On admission, she was moderately dehydrated, with scurf in the scalp and red buttocks. The eyes, mouth, throat and lungs, chest, and abdomen showed no abnormality.

Urine.—No pus cells, red blood-cells, or casts seen in the centrifuged deposit. There was a light cloud of albumin.

Blood.—Wassermann and Kahn reactions negative.

Stools.—*Proteus vulgaris* present. Repeatedly negative for *Staphylococcus aureus* and organisms of the salmonella and shigella groups.

Treatment and Progress.—On admission half-strength Hartmann's solution with 5% glucose was given by mouth, and during the first 18 hours there was no vomiting and no stools were passed. At 10 A.M. next morning one-eighth strength 'Ostermilk No. 1' was started, and in the next 24 hours there were three vomits and five small stools. At the end of that time two very large offensive stools were passed, and the feeds were changed to 'Nestlé's Sweetened Condensed Milk,' one-sixth strength, $2^1/_2$ oz. 3-hourly. At this time also the right eye was discharging, and penicillin 000 units intramuscularly b.d. was started. Cultures from the eye grew *Staph. aureus.*

On the 3rd day after admission fourteen stools were passed, and there were two vomits. At 4.30 P.M. the stomach was washed out and 3 oz. of subcutaneous saline was given. The parenteral fluid was repeated at 12 midnight and at 9 o'clock next morning. Streptomycin by mouth was also started, the dose and method used being that described by James and Kramer (1948). By 3.30 A.M. on the 4th day the *P. vulgaris* had been eliminated, and by 6.30 A.M. the stools were sterile on aerobic culture and remained so for 24 hours. After that time *Streptococcus fæcalis* and coliform organisms reappeared, but only in small numbers.

Progress during the next 2 days was satisfactory, the baby gaining 8 oz.

At 10.15 A.M. on the 7th day after admission there was sudden collapse. The baby was very pale, cold, and drowsy; her respirations were extremely shallow, her pulse was imperceptible, and her heart sounds could be heard only with difficulty. Despite injection of nikethamide, administration of oxygen, and later artificial respiration, the baby died at 45 A.M.

Necropsy.—No cause of the sudden death could be found, the only macroscopical changes being moderate fatty degeneration of the liver and well-marked congestion of the lower part of the small gut. No ulceration was seen. Cultures taken from the terminal ileum gave a very heavy pure growth of a coagulase-positive streptomycin-resistant *Staph. aureus* (heavy growth in streptomycin 1000 units per ml.). Unfortunately by this time the cultures from the eye had been destroyed, so the *Staph. aureus* from that source could not be tested for streptomycin sensitivity.

From the time that streptomycin was started by mouth, every stool passed was cultured on blood-agar, and at no time was *Staph. aureus* isolated. It is evident, therefore, that the organism in the gut had multiplied very rapidly.

The ability of *Staph. aureus* toxin on ingestion to produce acute food-poisoning is widely recognised, but it is less well known that in children the organism is capable of causing enteritis by multiplication in the gut. Felsen and Wolarsky (1942) and Draper and Brown (1946) describe several cases, three of those in the latter's series proving fatal.

It has also been shown (see Waksman 1947) that many of the normal organisms of the alimentary tract are capable of exerting antagonistic effects against staphylococci in vitro, and it is possible that the great reduction or temporary elimination of coliforms which follows the administration of streptomycin by mouth (Smith and Robinson 1945, James and Kramer 1948) may predispose towards such intestinal infection.

SUMMARY

A fatal case of enteritis in an infant receiving streptomycin by mouth is described.

A streptomycin-resistant coagulase-positive *Staph. aureus* was obtained in pure culture from the terminal ileum at necropsy.

It is suggested that the *Staph. aureus,* already present elsewhere in the body, was rendered streptomycin-resistant by the small amount of the drug absorbed from the gut, and that elimination of the normal intestinal flora may have contributed to the establishment of the staphylococcus there.

I am indebted to Dr. Ursula Shelley for permission to use the clinical notes of this case, to Dr. W. H. Hughes who performed the necropsy, and to Sir Alexander Fleming, F.R.S., for his advice and criticism.

TREATMENT OF LOCAL INFECTION WITH DIAMIDINES

F. KOHN
M.D. Prague.
SURGEON, ST. MARTIN'S HOSPITAL, BATH

CLARA D. CROSS
M.D. Sheff., M.R.C.P.
AREA PATHOLOGIST

DESPITE the successes obtained in the past eleven years in treating bacterial infections, some still remain unamenable to treatment. In a high proportion of these, gram-negative rods can be identified either alone or with other pathogens. We have tried to develop a technique for their elimination, mainly confining our attention to surface infections as before (Kohn et al. 1943).

The antibacterial properties of derivatives of the diamidines (Ashley et al. 1942) suggested that they were worthy of clinical trial.

Our first experiments were made with 2 : 2′-dibromo-4 : 4′-diamidino-α-γ-diphenoxypropane or 'Dibrompropamidine' and 2-iodo-4 : 4′-diamidino-α-ε-diphenoxyhexane or 'Iodohexamidine,' which in the absence of convenient short names will be referred to by their laboratory numbers M. & B. 1270 and M. & B. 1314. Owing to limitations in the supply of M. & B. 1314 most of our work was done with M. & B. 1270, but there seems little to choose between the two compounds as regards their action on staphylococci, except that when a strain in a wound has been found insensitive to one it has been sensitive to the other.

Bacteriological studies were made on each case together with appropriate sensitivity tests. Cultures were taken every day or at the time of each dressing, even when dressings were done more than once daily. The routine was to sow a loopful of discharge from the wound on a warmed blood-agar plate directly at the bedside. Blood-agar was used as a routine unless there was any indication for a special medium. In recording the results an arbitrary system of plus signs was used: ++++ indicated a plate completely overgrown, and + the presence of only three or four colonies, ++ and +++ being gradations between these. To prevent contamination of the culture-media with the drug, wounds treated

Urine.—Sp. gr. 1·028. No albumin or sugar. Microscopically normal.

Blood.—Red cells 6,200,000 per c.mm., Hb 120%, white cells 11,200 per c.mm. Blood-urea nitrogen, 18 mg. 100 ml. Wassermann reaction negative.

Electrocardiogram.—Normal limb leads (fig. 4) and chest leads.

Progress.—In view of the failure to find any other abnormality, and the presence of polycythæmia and symptoms probably related to hypertension, venesection 600 ml. was performed on Dec. 15. On Dec. 22, shortly before his discharge, he sat up in bed to look down at his breakfast tray, and this precipitated one of his attacks, an event which suggested that his symptoms might be due to a hypersensitive carotid sinus.

This was easily confirmed by light pressure over either carotid sinus which produced immediate cardiac asystole (fig. 5), and symptoms similar to those to which he is accustomed in his attacks immediately followed. The left carotid sinus was more sensitive than the right. Pressure on the left side was then made and kept up while a continuous electrocardiogram was taken. Immediate cardiac asystole was again produced; in 9 seconds he lost consciousness, and in 10 seconds began a generalised convulsion, whereupon the pressure was released (fig. 6).

The patient seemed to be sensible, if somewhat sensitive, and though he had retired from business his whole life was being seriously inconvenienced by these attacks, which were also a source of anxiety and uncertainty. Bilateral denervation of the carotid sinus was recommended.

Since both carotid sinuses were so extremely sensitive, it was thought advisable to expose each in turn, and to anæsthetise it, before proceeding with the stripping, so as to avoid any disturbance consequent on the manipulation of the vessels which would be required.

Operation (Jan. 16, 1947).—Dr. John Gillies gave thiopentone and cyclopropane; Mr. A. J. Slessor assisted. The bifurcation of the right common carotid artery was freely exposed through an incision along the anterior border of the sternomastoid, and the three vessels were covered with a swab soaked in 2% procaine solution. A similar procedure was next carried out on the left side. When, after 10 minutes, the operation on the right side was resumed, firm pressure on the carotid sinus did not give the abnormal response. The vessels were rigid from calcareous changes. Some 2% procaine was injected under the adventitia of the common, internal, and external carotid arteries for a length of 5 cm., after which the adventitia was removed by sharp dissection. On the left side the findings and procedure were the same. The wounds were closed without drainage, and the patient's convalescence was uneventful.

Follow-up in Outpatients' Department.—On Feb. 5, 1947 (20 days after operation), there had been no further attacks similar to his previous experiences, but a few short attacks of palpitation, coming on suddenly, lasting for a few minutes, and apparently slowly passing off had been experienced. It was considered possible that these were brief attacks of paroxysmal tachycardia, but were more probably simple sinus tachycardia. The patient had also had one attack of loss of vision for the central part of a page. This was the first for over a year and was considered to be due to vasospasm. General condition good. Heart clinically normal. Blood-pressure 210/120 mm. Hg. No change in the rate or volume of the pulse when either carotid sinus was pressed firmly.

March 5, 1947: No further attacks, but on several occasions has had a light feeling in the head as though falling through the air, accompanied by weakness of the legs but no faintness or dizziness, and lasting about 10 minutes—quite unlike his previous attacks. Blood-pressure 150/100 mm. Hg. He has been taking 'Theominal.'

April 16: Two weeks ago had an attack of "acute gastritis," when his doctor found a blood-pressure of 130/85 mm. Hg. Also had two brief attacks of central loss of vision. Blood-pressure 180/110 mm. Hg. Firm pressure over either carotid sinus has no effect on the pulse.

May 28: Quite well. Playing golf. Blood-pressure 170/105 mm. Hg.

July 9: Very well. No recurrence of symptoms after the operation six months ago. Blood-pressure 180/120 mm. Hg. Screening of heart showed no change from previous examination. Electrocardiogram normal.

Oct. 1: Very well. Blood-pressure 180/110 mm. Hg.

Jan. 14, 1948: No complaints. No recurrence of hi attacks. Now that his confidence has been restored he leading a normal life and playing golf regularly. No sym toms of postural hypotension. Heart clinically norm Radiography as before. Blood-pressure 190/110 mm. H Firm pressure over either carotid sinus has no effect.

On April 28, when last seen, he reported tw momentary attacks of giddiness, unlike those experienc before, but associated with a similar area of loss of visi in one eye. One attack occurred while walking down t main road and another while playing golf, but neith was sufficiently severe to interfere with what he w doing. Physical findings were as before, and, sin there has been no return of the sensitivity of eith carotid sinus, it may well be that these two brief atta of giddiness, accompanied by scotomata, were associat with vasospasm and related to his hypertension.

SUMMARY

A man of 61 with benign essential hypertension h frequent incapacitating attacks of giddiness, whi were shown to be due to hypersensitive carotid-sin reflexes.

Bilateral carotid-sinus denervation was carried o and during the succeeding year the patient has be free from his previous attacks. There have been adverse effects from the operation.

The possibility of this ætiology should be consider in similar cases.

FATAL STAPHYLOCOCCAL ENTERITIS DEVELOPING DURING STREPTOMYCIN THERAPY BY MOUTH

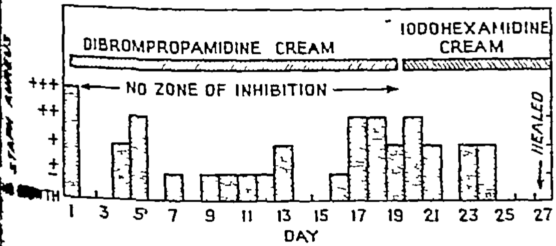
IVOR R. H. KRAMER
L.D.S. R.C.S.
ASSISTANT PATHOLOGIST, PRINCESS LOUISE CHILDRENS UNIT, ST. MARY'S HOSPITAL, LONDON

IT has been shown (Elias and Durso 1945, James an Kramer 1948) that when streptomycin is administered b mouth extremely high concentrations of the drug may b obtained in the stools (up to 9000 units per g.), and th growth of any sensitive organisms already present passing through the stomach during oral streptomyc therapy would be effectively prevented. Recentl (James and Kramer 1948) attention has been drawn to th possibility that, in patients receiving streptomycin b mouth, organisms remote from the gut may be rendere resistant by the small amount of the drug entering th blood-stream. This mechanism may provide a foc of resistant pathogens capable of reaching the gut an multiplying there, particularly in infants, where th bactericidal action of the gastric secretions is less tha in the adult. It seems probable that this unfortunat sequence of events occurred in the following case.

CASE-RECORD

A girl, aged 6 weeks. First child, normal pregnancy, ful term. Birth weight 6 lb. 7 oz.; weight on the 7th day 6 lb 10 oz. Breast-fed until the 17th day, when diarrhœa started there being twelve loose green stools that day, with sligh vomiting. The baby was taken to another hospital, " it was noted that she was severely wasted and that th liver and spleen were palpable. At that time the total leuco cytes numbered 7200 per c.mm. (stab forms 3%, neutroph chnique was evolved. Among the early cases were treated unsuccessfully with penicillic acid both in ous solution and in powder, application of the tter being painful. M. & B. 1270 and M. & B. 1314 applied in various ways with significant but not ncing results until used in powder form or incor- ated in amounts up to 5% in the new carbowax previously mentioned. In 14 successive cases of negative and coccal infection the infections were nated in not more than seventy-two hours. The nds if small were allowed to epithelialise spontaneously ath the serum scab which formed after successful treatment, or they were grafted in the usual manner ever all clinical results of the new treatment can be shown by the short stay in this hospital of ts with persistent sepsis. Owing to the lack of ate data for a truly comparable control series this ning of hospital stay cannot be expressed ically, but the change which has now taken place arent to everyone.

our early successful cases the appearance of a serum over large wounds, which rarely if ever became d thus, raised the question whether the scab might been the result of some local toxic or sclerosing of M. & B. 1270. This seemed unlikely in view of ose adherence of the scab to underlying granula- For this reason biopsies were done and serial s were made of tissues removed in the ordinary at the time of grafting three days after the start of ment. A typical specimen is shown in fig. 4, in h the edge of the serum scab can be seen with amous epithelium passing beneath it. The serum b is adherent to normal young granulations and vascular loops, and there is a complete absence of y pyknosis or polymorphonuclear reaction.



cteriological data in a case of traumatic ulcer of leg, showing of changing treatment from dibrompropamidine cream to amidine cream.

As a further test of local reactions another case was en. This was a long-standing varicose ulcer heavily cted with *Ps. pyocyanea* and in which two unsuccessful empts at grafting had previously been made. The iddle third of the wound was treated with M. & B. 1270 powder, the remainder being covered with soft-paraffin gauze. Fig. 5 shows biopsy specimens from the control and treated areas respectively. In the control the characteristic changes of an infected ulcer are visible. whereas the treated area shows a serum scab adherent to underlying new granulations devoid of any inflammation. Sections from other cases confirm these findings.

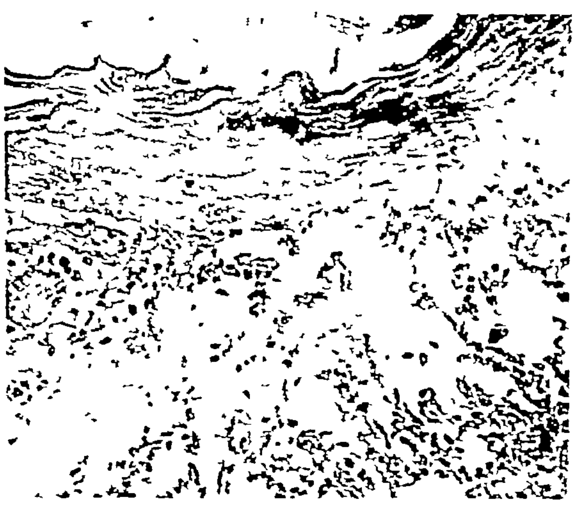


Fig. 4—Section of wound edge showing squamous epithelium extending under serum scab after treatment with dibrompropamidine. (× 225.)

The time that treatment should be continued is determined not only by the bacteriological findings but also by the type of wound and its pathology. With soft-tissue wounds results are quicker, and the time of treatment is shorter, than in lesions with much trophic disturbance, such as leg ulcers or those following neural lesions. In most cases significant infections can be eliminated in 72 hours and a decision made about further procedures such as grafting, secondary suture, or even natural healing.

We have found no evidence of general toxicity after the local application of M. & B. 1270 or M. & B. 1314, even when the former is placed in the peritoneal cavity.

ILLUSTRATIVE CASES

Intra-abdominal Sepsis

We have treated 7 cases of appendix abscesses, of which 3 were due to *Bact. coli* and hæmolytic streptococci, and 1 case of generalised peritonitis. This was done by placing 0·5 g. of M. & B. 1270 in the abscess cavity at the operation, one being a particularly severe case with an acutely inflamed friable cæcum. Tube drainage was provided in all cases at the time of operation, but dis-

with semi-solid vehicles were always carefully cleaned with saline before swabbing. Though too much saline on a surface wound might conceivably lead to a negative culture, the results obtained in the large number of cases treated suggest that this fear is unjustified. To satisfy the various opinions held regarding virulence tests on staphylococci note was made of colour changes, extent of hæmolysis, and production of coagulase. Direct films were not considered to be so useful as cultures in the treated wounds, because often bacteria seen in smears did not grow after effective local treatment had begun.

The accompanying table shows that the predominating bacteria were staphylococci and *Ps. pyocyanea*, *Proteus vulgaris* having been identified in only 3 of 32 cases, in contrast to experience in other hospitals. Diphtheroids have been isolated often, but we doubt whether these have much pathological significance in view of the clinical course of our cases once the major infection had been successfully treated. We include 3 cases of *Bact. coli* infection which occurred among 6 cases of mixed sepsis following recently treated appendicitis. Differential bacteriological studies have confirmed the findings of other workers that coccal infections are often overshadowed by *Ps. pyocyanea* in surface wounds, even after supposedly adequate treatment with sulphonamide or with penicillin (see fig. 1).

TREATMENT AND RESULTS

Initially the conditions selected for treatment were various surface lesions, including traumatic and varicose ulcers, open fractures with skin loss, indolent wounds, and an unhealed burn. In any local treatment of wounds it is necessary to ensure that purely mechanical factors do not prevent access of antibacterial agents to infected tissues. Pockets and sinuses may cause difficulties and if possible must be dealt with on first principles. Should the anatomy of the part restrict wound toilet, topical chemotherapy can be attempted, but the effect is not so dramatic as in more favourable cases.

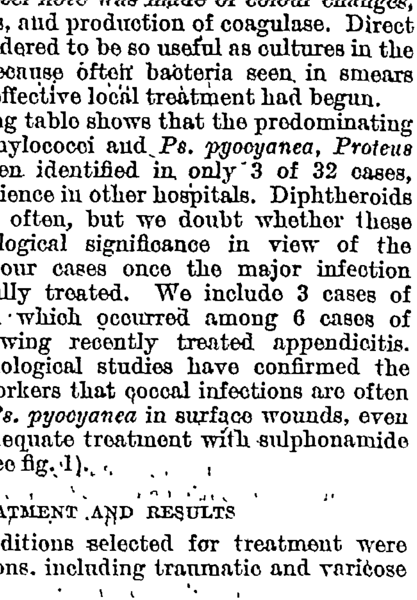

Fig. 1—Bacteriological data in a case of gunshot wound of thigh, showing prevalence of *Ps. pyocyanea*, and effect of dibrompropamidine.

At first we chose long-standing heavily infected varicose ulcers for investigating *in vivo* the action of the diamidines. Such cases are most convenient for assessing antibacterial techniques, especially against gram-negative rods, the principal pyogens outside the range of chemotherapeutic agents at present in general use. With the experience gained from these cases others likely to more difficult were treated.

There are three obvious ways in which an antibacter compound can be used for topical applications: aqueous solution, in a semi-solid vehicle, and as powd Initially, therefore, on obstinate cases we tested t effect of aqueous solutions. The use of wet dressings wounds is for technical reasons generally recognised unsatisfactory; so more attention was paid to t possibilities of semi-solid vehicles and later to the use powder. We believe that a 1:1000 solution of M. & B. 1270 may, in special circumstances, provide a useful adjuvant to surgery, but to find the optimal concentration for routine use *requires further* study.

We have examined several semi-solid vehicles generally popular for the local exhibition of antibacterial substances. Initially we used the Mumford base in which was incorporated 0·15% of M. & B. 1270 isethionat i.e., 0·1% of active product—but this and higher concent tions failed to eliminate gram-negative infections, becaus the inhibitory action of the 'Lanette wax.' Use was a made of the base devised by Todd (see Clark et al. 194 but it was abandoned for the same reason (see fig. 2).

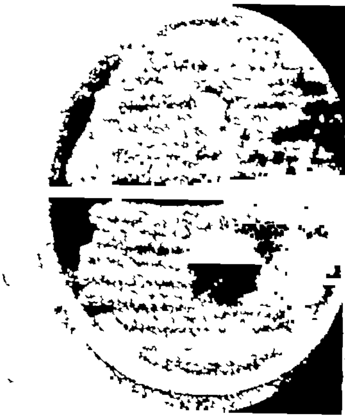

Fig. 2—Inhibition of *Ps. pyocyanea* by dibr propamidine when pure (below), but when in a cream (above).

The anticoccal action of M. & B 1270 and M. & B 13 is exerted in the presence of lanette wax probab because of the high activity of these compounds again gram-positive cocci compared with gram-negative rod Alternative vehicles have been examined. One consistin of carbowaxes, propylene glycol, and water containin 1–5% M. & B. 1270 shows the greatest promise, a further studies with it are in progress.

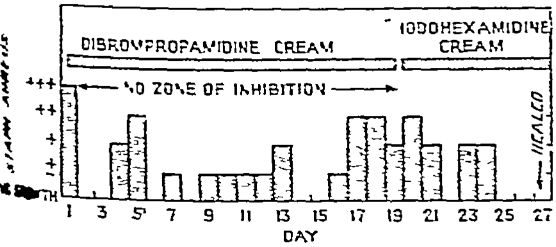
Dusting into wounds probably provides the best te of efficiency of any compounds being examined, and t is what we increasingly favour.

We have treated 12 cases of varicose ulcer, 7 traumat ulcers, 1 burn, 3 open fractures, 2 miscellaneous cases, a 7 cases of acute gangrenous appendicitis, but unfort nately in only 3 of the last was a precise bacteriologic examination possible. Some of these cases before comi under our care had received different treatments or treatment of any consequence. Of 16 cases with staphyl coccal infection 6 had had penicillin either alone combined with sulphonamide therapy.

The local infections fell into two groups; those d to persistence of staphylococci despite intensive trea ment with synthetic compounds or antibiotics, an those caused by gram-negative rods. Laboratory tes so often showed that the persistent staphylococc infections were insensitive or only slightly sensitive t penicillin that routine testing was abandoned. On case from which a penicillin-fast strain of staphylococcu was recovered made slow progress when treated wit M. & B. 1270 despite demonstrable sensitivity to it i vitro. Change to M. & B. 1314 eliminated the infectio in five days, and spontaneous healing took place fou days later (fig. 3).

We treated 10 cases of gram-negative infection wit one or more bacteria in various ways before a successfu chnique was evolved. Among the early cases were e treated unsuccessfully with penicillic acid both in ous solution and in powder, application of the ne being painful. M. & B. 1270 and M. & B. 1314 re applied in various ways with significant but not izing results until used in powder form or incorated in amounts up to 5% in the new carbowax s previously mentioned. In 14 successive cases of negative and coccal infection the infections were ated in not more than seventy-two hours. The ds if small were allowed to epithelialise spontaneously ith the serum scab which formed after successful treatment, or they were grafted in the usual manner. ver-all clinical results of the new treatment can be shown by the short stay in this hospital of ts with persistent sepsis. Owing to the lack of ate data for a truly comparable control series this ning of hospital stay cannot be expressed tically, but the change which has now taken place parent to everyone.

our early successful cases the appearance of a serum over large wounds, which rarely if ever became d thus, raised the question whether the scab might been the result of some local toxic or sclerosing of M. & B. 1270. This seemed unlikely in view of close adherence of the scab to underlying granula- For this reason biopsies were done and serial s were made of tissues removed in the ordinary at the time of grafting three days after the start of ment. A typical specimen is shown in fig. 4, in h the edge of the serum scab can be seen with



acteriological data in a case of traumatic ulcer of leg, showing of changing treatment from dibrompropamidine cream to xamidine cream.

mous epithelium passing beneath it. The serum b is adherent to normal young granulations and vascular loops, and there is a complete absence of pyknosis or polymorphonuclear reaction.

As a further test of local reactions another case was n. This was a long-standing varicose ulcer heavily cted with *Ps. pyocyanea* and in which two unsuccessful mpts at grafting had previously been made. The ddle third of the wound was treated with M. & B. 1270

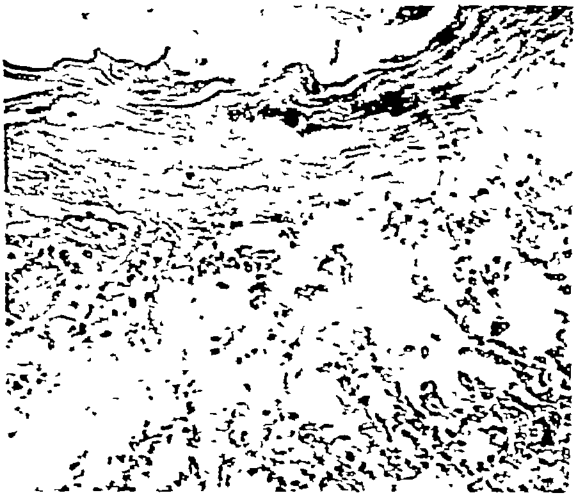


Fig. 4—Section of wound edge showing squamous epithelium extending under serum scab after treatment with dibrompropamidine. (× 225.)

powder, the remainder being covered with soft-paraffin gauze. Fig. 5 shows biopsy specimens from the control and treated areas respectively. In the control the characteristic changes of an infected ulcer are visible, whereas the treated area shows a serum scab adherent to underlying new granulations devoid of any inflammation. Sections from other cases confirm these findings.

The time that treatment should be continued is determined not only by the bacteriological findings but also by the type of wound and its pathology. With soft-tissue wounds results are quicker, and the time of treatment is shorter, than in lesions with much trophic disturbance, such as leg ulcers or those following neural lesions. In most cases significant infections can be eliminated in 72 hours and a decision made about further procedures such as grafting, secondary suture, or even natural healing.

We have found no evidence of general toxicity after the local application of M. & B. 1270 or M. & B. 1314, even when the former is placed in the peritoneal cavity.

ILLUSTRATIVE CASES

Intra-abdominal Sepsis

We have treated 7 cases of appendix abscesses, of which 3 were due to *Bact. coli* and hæmolytic streptococci, and 1 case of generalised peritonitis. This was done by placing 0·5 g. of M. & B. 1270 in the abscess cavity at the operation, one being a particularly severe case with an acutely inflamed friable cæcum. Tube drainage was provided in all cases at the time of operation, but dis-

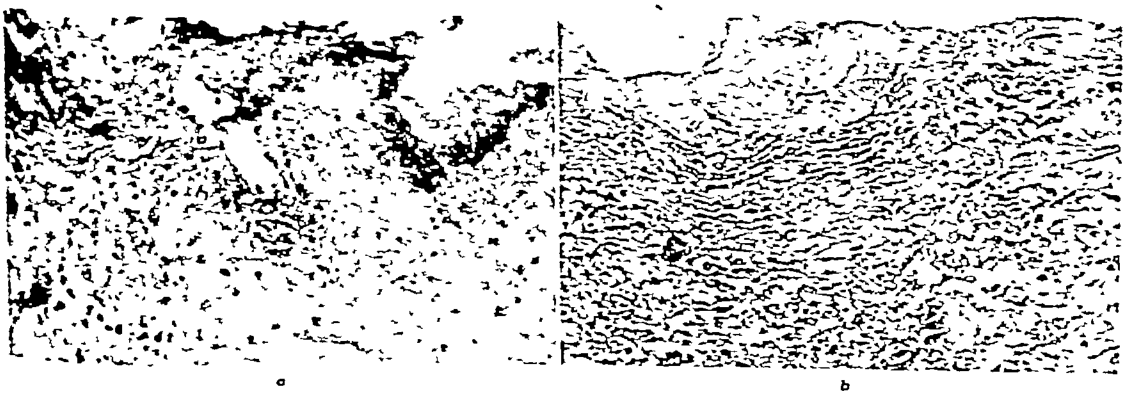

Fig. 5—Varicose ulcer : *a*, untreated area ; *b*, area treated with dibrompropamidine. (× 225.)

charge ceased so rapidly that tubes were removed within 48–72 hours, final healing taking place in not more than 14 days.

Case 1.—The case of general peritonitis secondary to gangrenous appendicitis was particularly instructive, because it demonstrated not only the action that M. & B. 1270 can exert in such infections but also its freedom from irritant effects. At operation a gangrenous appendix was found in pus which spread all over the abdomen. This pus was mopped out as far as possible, and films of it showed coliform organisms and streptococci; 0·5 g. of M. & B. 1270 was sprinkled round the cæcum, and the parietal wound was partially closed, with drainage of the pelvis. The patient, a man aged 19, was treated postoperatively with penicillin and sulphonamides, and detailed attention was paid to his fluid balance, but he never really responded and he died ten days after admission. At necropsy the findings were typical of such a case, except that in and round the cæcal area the visceral peritoneum was glistening and normal in all respects, without any fibrinous exudate or adhesions. In other words, were it possible to provide for a more widespread effect of M. & B. 1270 in the general peritoneal cavity, the life of such a patient might be saved.

Fractures

Case 2.—A man, aged 30, with an ununited open fracture of the tibia and fibula and considerable loss of overlying skin, was considered to need bone grafting. There was a scar measuring 18 sq. cm., covered with unhealthy granulations containing pathogenic *Staph. aureus.*

Powdered M. & B. 1270 was applied for 48 hours, at the end of which time culture was negative. A pedicle graft from the other leg was applied in two stages, and complete healing took place by first intention. The donor site was open and became infected with the same bacteria. Application of M. & B. 1270 for 48 hours cleaned this area, a Thiersch graft was applied, and the wound completely healed in a week.

Case 3.—A man, aged 26, had sustained an open fracture of the right tibia close to the ankle three and a half years earlier. Immediately after the accident he had been admitted to hospital, where he had remained for twelve months, undergoing first-class surgical treatment, with adjuvant penicillin and sulphonamides for the sepsis which developed. The sepsis had persisted, and further local and general penicillin therapy had been given without effect. Bony union had ultimately taken place, but he had been left with a large bone and skin defect measuring 4 cm. across and 2·5 cm. deep. In various hospitals attempts had been made without success to control the local sepsis and effect a repair. When we saw him he had the discharging wound just described, from which a pathogenic staphylococcus was isolated. M. & B. 1270 powder was dusted into the wound for 2 days. A sterile serum scab formed. This was removed, a Stent graft was applied, and the wound healed in a fortnight from the time of admission.

Varicose Ulcer

Case 4.—A man, aged 71, had had a varicose ulcer for many years. It measured 71 sq. cm. and was covered by typical necrotic material. *Ps. pyocyanea* was obtained in pure culture. M. & B. 1270 powder was applied twice daily for two days and then daily for two more days, at the end of which the wound became sterile and was immediately successfully grafted.

Reinfection.—In the early cases treated it was found that, if grafting was delayed, the wound might soon become reinfected with gram-negative bacilli. Cultures made from the skin edges just beyond a wound rendered sterile by M. & B. 1270 powder yielded a growth of similar gram-negative bacilli, and it seems that from these edges a wound may become reinfected unless countermeasures are taken. The procedure adopted initially was to dust the wound twice daily, well beyond the skin edges, with a very finely ground powder applied with a pepper-pot with many small holes, the area afterwards being covered with plain gauze. We used the small screw-capped bottles in which the "bijou" slopes of medium are contained, removed the rubber disc, and made small holes in the screw top. A sulphanilamide insufflator might be used for dusting.

DISCUSSION

Many patients had received various local applicatio before M. & B. 1270, in powder and more recently carbowax base, was applied with good effect, but t previous long treatment might have rendered the infe ing strain more sensitive to the new agent. Two fre cases of varicose ulcer, both of six months' durati were therefore selected. Neither case had had a specific treatment and both were infected only w *Ps. pyocyanea*. Clinically the effects were equally striki because discharge ceased and the raw surface beca covered with a serum scab firmly adherent to underlyi healthy granulations. To save the time necessary spontaneous healing these wounds were successfu grafted forthwith despite the fact that natural heali seemed likely to take place.

The results of treating ordinary surface wounds wi M. & B. 1270 in semi-solid vehicles justify its use a local application for the routine treatment of superfic infections. No special storage precautions are necessa The range of activity appears to be governed by vehicle used. For infections in which gram-negat rods predominate a carbowax base will be necessa but M. & B. 1270 in Todd's cream is effective in coc infections, besides relieving the pain in some staphy coccal infections, a property which does not seem simply to the bland nature of the base. Two cases persistent painful staphylococcal ulcers had had, with effect, various applications including cream bases exac similar to that used to exhibit the new compoun Within a matter of hours relief was obtained and c tinued, the most likely explanation being that prolife tion of virulent staphylococci was checked; recov was rapid.

It is contrary to generally accepted ideas about inhibition of bacterial activity that a single compo can provide an effective local treatment of surf infection by such morphologically different bacte as those under review. However, Bernheim (19 has shown that a simpler diamidine, 'Propamidi inhibits the oxidative metabolism of certain gra negative bacilli.

In all our treatments the results do not seem to ha depended on the quantity of compound used so mu as on how it was used. We have not finally decid whether better results accrue from the application pure powder than from admixture with a suita diluent. It is likely that the indications for and metho of using M. & B. 1270, and M. & B. 1314 in powder fo will make skilled supervision necessary to obtain t best results and avoid a foreign-body reaction, but t use of existing cream preparations is only limited by th range of antibacterial action. It is also likely th cream preparations can in some circumstances beneficially used after initial treatments with powder.

Touching the methods available for recording t progress of wounds, the rate of healing is not necessar the best way of recording the effects of aids to trea ment. Many infected wounds for a while make fi progress which becomes slower as fibrous tissue develo The early application of grafts, and the use of seconda suture whenever possible, introduce an artificial, b highly desirable, complication to studies of healing rat Bacteriological studies on wounds undergoing treatme may, if taken at their face value, be misleading becau positive cultures can be obtained despite obvious clinic improvement as soon as antibacterial compounds sta to exert their effects.

SUMMARY

The effects of dibrompropamidine and iodohexamidi on infected wounds have been examined.

Dibrompropamidine powdered *into surface* wound inhibits infections with gram-negative bacilli, *Ps. py*

[illegible], and *Bact. coli*, and it may find a place in the treatment of appendix abscess and resultant peritonitis.

Dibromopropamidine in castor-oil cream provides a [illegible] non-toxic practical alternative to sulphonamides and penicillin for the treatment of surface infections with gram-positive cocci. In a carbowax polyethylene-glycol base its action on gram-negative organisms is also manifest.

From the limited experiments made with iodo-[illegible] it seems to provide a useful alternative to dibromopropamidine when bacterial strains initially resistant to the latter are encountered.

We have drawn on the knowledge and experience of Dr. [illegible] in the field of chemotherapy, and we are [illegible] to him for this and for his vision regarding many problems still outstanding.

Our thanks are due to Miss Daphne Miller and Mr. J. B. [illegible] for much technical assistance, to Messrs. May & Baker Ltd. for supplies of the compounds used, and to [illegible] Gillette Industries Ltd. for the photomicrographs.

ALGINATES IN ENDAURAL WOUND DRESSING

E. R. GARNETT PASSE

D.L.O.
ASSISTANT AURAL SURGEON,
KING EDWARD MEMORIAL
HOSPITAL, EALING

GEORGE BLAINE *
L.R.C.P.E.
STRANGEWAYS RESEARCH
LABORATORY,
CAMBRIDGE

The success of endaural operations, especially the fenestration operation, largely depends on a suitable postoperative dressing. Unless one obtains a dry cavity which heals by first intention in a minimum of time, [illegible] is complicated by excessive granulations, especially over bared bone.

Until recently one of us (E. R. G. P.) has used an [illegible] cellulose packing which, as it liquefies, can be sucked out of the cavity on the tenth day. This has [illegible] proved an advantage over other materials with which it is necessary as a routine to perform four or five dressings, the first always under anæsthesia (Passe 1947).

Tumarkin (1948) has also emphasised the importance of postoperative dressings in transmeatal atticotomy, recommending the use of a gel formed from a mixture of penicillin and 'Zelex,' which is mainly composed of an alginate base.

In a search for an ideal endaural dressing, alginate materials were submitted to extensive trials during the past six months. Based on the work of one of us since 1944 (Blaine 1946, 1947a and b), a wide range of materials has now been made available with properties which make them eminently useful for this purpose.

Alginate is an extract of the brown seaweeds growing on the Scottish and Irish shores, the parent substance being alginic acid, a polyuronic acid whose sodium salt combines with calcium ions to produce an insoluble gel. This reaction makes it possible to produce fabrics like [illegible] gauze, and foam; it has been found non-antigenic, sterilisable by heat, hæmostatic, and slowly absorbable in living tissue according to the vascularity of the tissue into which it is placed. Alginate is rendered soluble in solutions of sodium salts. The introduction of a variable percentage of sodium ions into calcium-alginate fabrics makes possible the production of a range of materials of variable solution-rate and absorption-rate. Antibacterial substances can be combined with these in the course of production.

Advantages of Alginate Dressing.—One of us (G. B.) has found in experimental surgical studies that calcium alginate is usually slowly absorbable in living tissue without inducing excessive formation of fibrous tissue. It is hæmostatic and a poor culture medium for micro-organisms. Alginate materials in which the percentage of sodium ions is raised by industrial chemical treatment over that of calcium ions are absorbed with far greater rapidity and with a minimal reaction. The speed of absorption or of solution again depends on the vascularity of the tissue into which it is placed. Thus, as an endaural wound dressing, where meticulous hæmostasis has been achieved and where there is only a little serous oozing, the alginate gauze or wool displays the following properties:

(1) Where the dressing is in contact with the oozing surface it is converted into a smooth jelly.

(2) Parts of the dressing not in contact with a moist surface remain, on the whole, unaltered.

(3) It can be easily packed into crevices, conforming closely to the contour of the surface to which it is applied. Dipped into saline solution, Ringer's solution, or water (according to the grade of material used) immediately before use, it becomes a truly plastic dressing which securely keeps skin flaps in place.

(4) The alginate dressing can be left in situ for the whole period of convalescence without being changed.

(5) Removal is effected by gentle withdrawal or by dissolving the material in the solvent at the grade used (saline solution, sodium citrate, or water). In the case of the water-soluble alginate grades a good part of the dressing will liquefy by the time it is to be removed.

Composition.—In these trials the following grades of alginate ribbon gauze and wool have been used:

(*a*) Calcium alginate containing cetyl pyridinium bromide (C.P.B.), an antibacterial agent akin to cetrimide ('Cetavlon.')

(*b*) 80% sodium-calcium alginate containing C.P.B.

(*c*) 20% sodium-calcium alginate containing C.P.B.

(*d*) 20% sodium-calcium alginate with 5% borax, containing C.P.B.

CONCLUSIONS

Alginate dressing is by far the most satisfactory for the aural surgeon. It can be left in situ for three or four weeks; it prevents excessive formation of granulation tissue; it obviates the patient's anticipation, fear, and discomfort of repeated dressings; and it reduces the work of the aural surgeon. Sulphadiazine and/or 'Phenoxetol' can be added to alginate dressings, though the material is a deterrent to bacterial growth owing to its content of cetyl pyridinium bromide. On removal of the dressing the cavities always appear smoothly healed and clean with the healthy pale-pink skin flap held firmly in place over the fenestra.

When used after radical endaural mastoidectomy the alginate dressings proved themselves equally excellent. In these cases the dressing was applied after preliminary sprinkling of the wound with sulphadiazine and penicillin powder. The dressing was usually changed after seven to ten days, when the healing cavity was repacked with a fresh alginate dressing. Both the wool and gauze were found to be satisfactory.

The Scottish Research Association, Messrs. Courtaulds Ltd., and Optrex Ltd. provided chemical information and materials for this trial.

Reviews of Books

The Mechanism of Abdominal Pain

V. J. KINSELLA, CH.M., F.R.C.S., F.R.A.C.S., surgeon, St. Vincent's Hospital, Sydney. Sydney: Australasian Medical Publishing Co. 1948. Pp. 230. 32*s.* 6*d.*

IN this book Mr. Kinsella attempts to connect abdominal pain with particular nerve paths and to explain the phenomena of abdominal sensation anatomically. He begins with a historical outline of past research, which makes it clear how difficult the subject is. His main thesis is that pain nerves in the viscera are of splanchnic origin and do not differ essentially from sensory nerves elsewhere. Clinical experiments are cited which seem to show that inflamed organs are sensitive to pressure; but the explanation of why it is possible painlessly to cauterise and cut intestine or stomach withdrawn from the peritoneal cavity is not very convincing. The existence of an "irritable focus" substance acting in the central nervous system is postulated, but no evidence for it is brought forward except the argument of analogy. Clinically the author is undoubtedly right when he insists that deep tenderness is the best guide to the inflamed viscus. The later chapters, in which the pains of different diseases are explained in the light of the author's hypotheses, are very interesting.

The emotional make-up of different people is so different that their responses to pain are scarcely comparable; and the difficulty in arriving at truth in studies based on subjective expressions is extreme. This book, if it does not much advance the knowledge of visceral pain mechanism, is stimulating; and Mr. Kinsella's critical attitude to previous work will be a great help to anybody entering this field of investigation.

Present Status of the Surgical Treatment of Hyperthyroidism

WARREN H. COLE, M.D., professor and head of the department of surgery, University of Illinois; EDSON FOWLER, M.D., assistant in surgery in the department. Springfield, Ill.: Charles C. Thomas. Oxford: Blackwell Scientific Publications. 1948. Pp. 81. 10*s.* 6*d.*

THIS brief monograph comes from the department of surgery in the University of Illinois, Chicago. Though it does not attempt to cover the whole field of thyroid surgery, it effectively displays the more important features. The authors' aim has been to emphasise subjects of moment at the present time, and this they do without waste of words. The position of the antithyroid drugs is fairly and clearly summarised; though (unless the patients are carefully selected) it seems over-optimistic to suggest that more than half of those treated with propyl thiouracil will experience lasting remissions. The little said about the use of radioactive iodine in toxic goitre is not in its favour. Preoperative treatment is well described, as well as the criteria by which safety for operation is determined. The operative technique seems to differ little from that practised in Great Britain, and indeed the whole subject seems to have reached very much the same position in the United States as here.

Jaundice

Its Pathogenesis and Differential Diagnosis. ELI RODIN MOVITT, M.D., acting chief of medicine, Veterans Administration Hospital, Oakland, California. New York and London: Oxford University Press. 1947. Pp. 261. 42*s.*

A BOOK devoted to jaundice is particularly welcome at the moment because of the current widespread interest in disease of the liver, the recent extensive epidemics of infective hepatitis, and the importance of accurate diagnosis before treatment. The first part of this work, devoted to anatomy, physiology, and diagnostic procedures, is reliable and critical. Unfortunately though there are some 180 references at the ends of the chapters, the text mentions hardly any of them, and the reader is therefore left with no ready means of verifying such surprising statements as that "a number of individuals diagnosed as diabetes, and being treated as such, actually suffer from liver insufficiency rather than the insufficien of insulin," or that "the liver serves as the largest dep of vitamin C." Despite this, part I is a comprehensi and useful contribution to the literature on tests of li function. Part II, which gives a textbook description the three main types of jaundice—hæmolytic, parench matous, and obstructive—does not maintain the sa standard. The section devoted to toxic hepatitis is we and the relation of nutrition to liver disease is alm entirely relegated to a misleading footnote in which terms toxipathic and trophopathic are incorrectly us again without reference to original papers. A startli omission is the absence, in a long discussion of arsph amine jaundice, of any reference to syringe-transmitt hepatitis. Nevertheless the book as a whole conta information of great value to all responsible for the c of jaundiced patients.

Introduction to Diseases of the Chest

(3rd ed.) JAMES MAXWELL, M.D. Lond., F.R.C.P., ph cian, to the Royal Chest Hospital, and to the Minist Mass X-ray Unit. London: Hodder & Stoughton. 1 Pp. 308. 12*s.* 6*d.*

IT is seldom difficult to find technical faults i textbook for students: presentation of a subject sim logically, and without argument, inevitably invol some over-simplification. This book is not with such faults, but it is nevertheless a very good bo omitting little that is important. The present edit differs from the second chiefly in including radiogra as part of physical examination of the chest rat than as the first of the special investigations— enhancement of status designed to impress its importa on the student.

The opening chapters, dealing with history-taking physical examination, are particularly helpful, and i comforting to find so experienced and dogmatic author hedging a little over the exact significance bronchovesicular breathing. The ætiological classificati of such conditions as lung abscess and pleural effu are precisely what the student needs; that concern carcinoma of the bronchus is a fraction too sketc The illustrations, gathered together at the end in form of an atlas, make a moderately good representat collection.

First-Year Physiological Technique (London: Stap Press. 1948. Pp. 84. 7*s.* 6*d.*).—This excellent booklet written in so light a vein that it is tempting to make a lau tory pun on Dr. Alex Comfort's surname. There is a pennyworth on every page and no student should be without

Essays on Historical Medicine (New York: Frol Press. 1948. Pp. 220. $5.).—Dr. Bernard J. Ficarra's b is a series of essays on more or less related subjects—a p pourri of persons and events in medical history. In gene the outlook is surgical, and he gives pride of place to the ra progress of American surgery, more particularly abdomi surgery—progress dramatic in scope as well as in spe Among the more general essays the references to surgery Shakespeare claim attention, as do the details of famous m and women who have suffered from some physical disabil and yet overcame this and lived to benefit their fellow m

British Juvenile Courts (London: Longmans, Gr for the British Council. 1948. Pp. 44. 2*s.*).—Mr. John A. Watson begins his short book by citing the cases of a b of 13 hanged at Maidstone in 1831 for theft, and of another 9, sentenced in 1833, but not executed, for breaking a wind From this starting-point he describes the circumstances procedure of the modern English juvenile court, and disposal of offenders. The text is readable and accura and though it tends in places, especially in its choice illustrations, to become an apologia for the system it describ it will prove useful as a source of facts both in England a (as its publication for the British Council foreshado abroad. The author is himself a court chairman, and reasonableness and humanity of his attitude might well an object lesson to those who deal with adult offenders, wh the contrast with 19th century penology is less evide The Lord Chancellor, Viscount Jowitt, contributes a judici preface.

THE LANCET

LONDON: SATURDAY, OCT. 23, 1948

Prefrontal Leucotomy

"PSYCHIATRISTS have been consistently pessimistic about modern physical methods of treatment of mental illness, and consistently wrong," said Dr. DESMOND CURRAN in his Croonian lectures to the Royal College of Physicians last week. Among such methods, prefrontal leucotomy, first done in Lisbon in 1935, has now a long enough history to justify some assessment of its value. Experience has shown that the plane of the cut is important. If too far back it may cause profound stupor, severe personality changes, or even death; and the most satisfactory plane proves to be just in front of the tip of the anterior horn of the lateral ventricle, in about the line of the coronal suture. Dr. ALFRED MEYER, who, at the London County Council's Central Pathological Laboratory, has examined a number of brains in which the operation has been done, has found great variety in the site of the cut; only 10–15% of the corticothalamic fibres may have been divided, and in one case the surgeon had failed to hit the brain at all. The mortality is low, however, and was given in the Board of Control report on prefrontal leucotomy[1] as 3 per 1000. Convulsions are an occasional sequel, but are usually isolated, and seldom persist beyond eight months after the operation. Dr. CURRAN mentioned two patients with idiopathic epilepsy who had no further fits after prefrontal leucotomy. Other occasional sequels are temporary urinary or rectal incontinence, apathy, and transient disorientation. The blood-pressure falls somewhat, and stays a little lower than before operation, even in hyperpietics. The appetite improves, and there may be a period of gross overeating. The patient commonly looks younger and handsomer, and sexual desire is increased, though it usually returns to normal within about a year. A severe reaction after the operation does not necessarily mean a bad prognosis: on the contrary, it almost seems to carry a good one. Common reactions are apathy, irritability, confusion, euphoria, or restlessness; but these gradually wear off, especially if the patient is given opportunity for reablement. W. FREEMAN and J. W. WATTS relate the response to the previous personality of the patient, and to the plane of the cut—finding that euphoria is associated with a forward cut, and apathy with a cut placed far back. The inertia gradually wears off, however, and often gives place to a shallow, cheerful, prankish mood. The attitude of the patient towards incontinence is objective. "What's the weather like with you?" asked one, passing water while she telephoned. "It's raining here."

Dr. CURRAN noted that American opinion is less optimistic than British opinion about the results of the operation. Americans emphasise the fatigability of these patients, their shallowness, and their lack of perseverance; but in Dr. CURRAN's experience these drawbacks are commonly less after six months, and FREEMAN and WATTS found some of their cases doing better after five years than after two. The patients have less capacity for self-blame, and in their work they favour speed before accuracy. F. L. GOLLA holds that their power of ethical evaluation is impaired. Ultimately, however, the success of the operation turns on how the patient feels, what he can do, and what others make of him. His behaviour and capacity must be compared with these things before operation, and his capacity for social relationships must be discovered by asking his friends about him. If they complain that he is not perfect it is well to remember that people in whom the corticothalamic tract remains undivided are not always easy to live with, and that a satisfactory family is necessary for a good recovery. Jewish patients often respond well because family feeling is strong among the Jews. A relatively imperceptive husband or wife, one not easily perturbed by trifles, is a great standby. Those who report, for instance, that a patient was "aggressive" after leucotomy tell nothing unless they say whether his family minded his aggressiveness. Relatives can often estimate the meaning of a patient's behaviour better than the doctor can; and they may be especially helpful when operation is being contemplated, since they can judge whether the patient is suffering real distress of mind or not. Dr. CURRAN mentioned the case of a complaining patient whom he took to be feeling little genuine distress till a member of her family said: "She's not querulous for the sake of being querulous, but because she is anxious and afraid." Emotional tension is the main indication, and the prognosis is related to its degree —to the "amount of tortured self-concern" the patient suffers. Nevertheless some schizoid patients who show little sign of emotional tension respond well —evidence that despite their outward calm their emotional response to their ideas is still strong. A deteriorated schizophrenic, on the other hand, "looks and acts the same with or without his frontal lobes." The prepsychotic personality has some bearing on the result. Those who had a cruel streak, or sought refuge from responsibility, possibly in alcohol, often do badly. The operation has been used in an attempt to reduce the restlessness of hyperkinetic mental defectives, but without much success; those who improved relapsed quickly. On the whole, the better the intelligence the better the result.

It is noteworthy that in America the operation, though not greatly valued for mental states, has been used considerably in the treatment of intractable pain—for instance, the pain of incurable cancer. Though it does not ease the pain, leucotomy may free the patient from the dread of it, and for some reason he then finds it altogether more bearable. New versions, including transorbital leucotomy[2] and ablation of part of the frontal lobes, are still on trial.

Advances in Microscopy

IN the last fifteen years three new methods of microscopy have been developed which promise great advances in our knowledge of biological fine structure. The principles of phase-contrast microscopy were demonstrated by ZERNIKE in Holland in 1934; the first practical compound electron microscopes were built by RUSKA and MARTON in the *same year;* and since 1943 BURCH has constructed the first high-performance reflecting microscope.

With the development of the apochromatic objective in 1878 the lens microscope rapidly attained a performance approaching its theoretical limits. Oil-immersion lenses with numerical apertures approaching 1·5 can resolve objects down to a *third* of the wavelength of light—for sodium light this would correspond to a particle diameter of 2000 Å, or 0·2 μ. By using ultraviolet light of shorter wavelength the resolving power can be further improved to below 1000 Å; but, since glass is opaque to ultraviolet, quartz-fluorite lenses have to be used. Unfortunately, these lenses are monochromatic, so they can only be used for photomicrography and accurate focusing requires a series of trial-and-error exposures. The limit of this technique is set by the opacity of the objective in the far ultraviolet region. However, many biologically important compounds (*e.g.*, nucleic acid) strongly absorb ultraviolet light of selected wavelengths, and the U.V. microscope has therefore proved valuable for qualitative and quantitative estimations of such materials within the cell. This method has been widely used in studies of malignant cells, and such studies can be made on the living cell.

The phase-contrast microscope is also particularly valuable in the study of living cells, though in resolving power it is no better than the normal lens system. When a completely transparent colourless object is viewed in the ordinary microscope, differences in refractility in parts of the object are visible only at the *boundaries* between the regions of different refractive index. In this way the nucleus, chromosomes, cilia, and flagella are seen bordered by light or dark lines. Under phase-contrast illumination the effect produced is that of staining all refractile objects with a neutral grey tint whose depth is a measure of the refractility of the object. The internal details of many of these refractile bodies can be studied; vacuoles in a flagellum and chromosomes in the nucleus are often clearly seen. Phase-contrast illumination can be adapted to any ordinary microscope, but it requires a special condenser and objective. The condenser has an annular stop, so that a ring of light is brought to a focus at the back of the objective. The "phase-plate" in the objective is a flat glass plate with an annular channel a quarter of a wavelength in depth cut in its surface; the plate is so placed that the image of the condenser annulus falls exactly in the groove, and the groove is darkened to absorb part of this undiffracted light which passes through it. Diffracted light from the object passes through the remainder of the phase-plate; it is th interference of the undiffracted and diffracted beam which produces the *intensity differences* in the fin image. This method of examination is not suitab for thick layers of tissue, thick cells, or cells whos *cytoplasm* is densely packed with refractile granule But individual cells in tissue-culture are ideal objec for it; cilia and flagella give clear "solid" image and not fictitious diffraction patterns; the structur of striated muscle-fibres and banded chromosom is sharply defined; and bacteria, spirochætes, an similar bodies are revealed almost as well as by dark ground illumination. HUGHES and BARER hav shown some of the possibilities of this method i their studies of cell division and the structure muscle-fibres.

The new reflecting microscope which Mr. C. BURCH, PH.D., F.R.S., is working on at Bristol ove comes many of the defects inherent in a lens micr scope.[1] The mirror objective is completely achr matic and has a minimum of spherical aberration, wit *an effective numerical* aperture of 0·65, but it h a working distance of nearly 2 cm. These featur give it the optical performance of a 4 mm. le objective with the working distance of a lo power binocular. The advantages of this in studi employing microdissection or involving high temper tures and pressures can readily be appreciated. A *oil-immersion component can be added to raise* th numerical aperture to 0·98, and future models a projected with the resolving power of a norm 2 mm. oil-immersion lens. These achromatic systen have the enormous advantage of complete inte changeability of visual and ultraviolet illuminati sources, without change of focus. Since the reflecti *power of a mirror surface can extend into* the far ultr violet, well beyond the limits of a quartz-fluorit lens, the resolving power of this new microscop promises effective magnifications several times thos achieved with the U.V. lens microscope. The reflectin microscope is at present an elaborate and exceedingl costly apparatus. So far its gourd-shaped mirror have required more than 100 hours of skilled an accurate hand-polishing, but the problem of shapin them mechanically is being energetically studie The achromatic characteristics of these microscope are likely to find their most valuable application i absorption spectrophotometry of living and fixe material.

The electron microscope *owes its origin* to the fac that narrow conical pencils of electrons moving a high velocity can be focused by magnetic or electro static fields precisely as light is focused by a len system. The electrons are emitted by a hot fila ment and are accelerated along the microscope by high-voltage source. Very accurate *control of* th voltage produces a "monochromatic" beam o electrons of constant velocity. Most modern electron microscopes use magnetic lenses, which are short solenoids with accurately ground *internal pole-pieces*; the focal length of the lens can be altered by varying the current passing through the solenoid, so a large *range of magnifications can be achieved* with a single lens system. *The numerical aperture of the objective* only about 0·001, but, since the equivalent electron wavelength is 5×10^{-10} cm., this gives a resolving power of 50 Å—some forty times better than the best results with the optical microscope. Experimental models have been built to resolve 10 Å, which should make visible spherical molecules consisting of about [illegible] atoms. The possibilities of the instrument for biological research are therefore enormous. That it has not yet realised the dreams which it first inspired is due to difficulties in the preparation and mounting of the specimen, which must be less than ·1 μ thick and, since the microscope is evacuated to a very low pressure, must also be completely dry. Thick specimens absorb too much of the energy of the beam, and, apart from their consequent opacity, may be destroyed by the heat which is liberated in them. For this reason the most successful electron micrographs have been of such subjects as viruses, bacteria, flagella, and small muscle and tendon fibres. These are usually examined dried on a thin film of plastic. For larger objects it has been necessary to develop new methods of preparing very thin sections. The ordinary microtome will cut sections of 1–2 μ with difficulty; below this limit the plastic flow of the embedding medium prevents the knife from cutting. By using cutting speeds of several hundreds of feet per second, the knife blade being mounted on a high-speed flywheel, objects embedded in wax or camphor can be cut sufficiently thin for observation in the electron microscope. Artefacts produced in the specimen on drying, which denatures the proteins and destroys much of the characteristic structure, cannot be readily eliminated. "Freeze-drying" by the Altmann-Gersh technique is one possibility; here the material is frozen in isopentane cooled to −180°C and is dried by vacuum evaporation of the ice at −30 to −70°C under a pressure of 0·0001 mm. Hg. Attempts have also been made to mount the living specimen in an airtight cell, permitting it to be examined wet, though so far with little success.

[2] Freeman, W. *Lancet*, Sept. 4, p. 371.

Owing to the very low aperture of electron lenses their depth of focus is enormous—greater than the thickness of the specimen examined. There is therefore no "modelling" or depth effect in the photographs; overlapping fibres, for example, merely appear denser at the point where they cross. This difficulty can be overcome either by rotating the specimen holder and taking stereo-electronmicrographs, or by an elegant shadow technique which is becoming widely used. The object is placed in a high vacuum and obliquely bombarded with a rectilinear stream of heavy metal atoms. When examined afterwards in the electron microscope the deposit of heavy metal appears as a fictitious "shadow" reproducing very accurately the relief of the specimen. (Since the deposit of gold atoms represents the "light" and not the "shadow," it is usual to print the photographs obtained in their negative form.) A technique equivalent to that of histological staining is being developed. Normal stains are not significantly different in opacity from the rest of the tissue, but heavy metal compounds, preferentially absorbed at certain points in the structure, can be readily seen in the electronmicrograph because of their high density. There is a wide field here for further work on the intimate—one might almost say ultimate—structure of the molecular complexes present in biological systems.

Recovering from Tuberculosis

A CONVALESCENT patient, returning to the sanatorium after three days' absence on urgent business, said, "My friends are going to be my downfall, I can see." Bronzed, a stone heavier, and looking as if he had spent his year on a world cruise, he had been greeted with back-slappings (on his A.P. side), nudges (in his pneumoperitoneum), loud cries for drinks all round, and entreaties to make a night of it. It was a new experience for him to have to play the wet-blanket; and he hated it. How long had he got to be "odd man out"?

No guarantee can be given to a convalescent tuberculous patient that he will never break down again. But if he can maintain good health with freedom from all signs and symptoms of active disease for five years he will be able to regard himself as "cured." The maintenance of good health will depend almost entirely on his observance of self-imposed restrictions; and five years is a large slice of life to spend walking delicately, especially for a person who shows no visible stigma of disease or disability, who feels well in himself, and who perhaps has social or economic reasons for wishing to conceal his true condition. The tests of graduated exercise at the sanatorium will have determined to some extent how much exertion he ought to undertake each day to begin with; and the rules of rest and relaxation will have been learned, practised, and acquired as habits—rules such as avoiding "getting out of breath," going to bed early, keeping statutory "rest hours" during the daytime, and, above all, resting whenever tired. These habits are easy enough to observe in a community where everybody else is observing them: it is when the patient gets home that his moral fibre is tested. How can he be helped? At this point it is essential to discover what circumstances brought about his illness. His work? His leisure? Or his whole attitude towards the business of living? This is a most important question, for on its answer depends his successful reablement—and prognosis.

Sometimes it is possible to contrive a change from an uncongenial job to one less exacting and more satisfying. But not often. As a general rule it is far better for the patient to return to the job he understands—so long as he does not positively detest it—than to switch to a new job with its new worries and uncertainties: a clerk is better advised to return to his office stool than to embark on the more hygienic hazards of poultry-farming. Naturally, at first he will only be able to engage in part-time work, and his hours should be arranged so that he arrives late and leaves early, thus avoiding the rush-hours on trams, tubes, and buses. Every effort should be made to enable him to lunch in comfort and to break his working hours with a proper "feet-up" rest during his lunch interval. With the present labour shortage, employers are more willing than ever to make such concessions, even for the less highly placed members of their staffs.

But the 40-odd hours per week spent at work are a far smaller source of danger than the 120-odd hours of so-called leisure and the tensions caused by the many claims of interpersonal relationships during these hours. For many men and women life begins after the day's work is done. Shortage of help in the home spells a full-time burden for the home-maker. Can either husband or wife bear to lie with the feet up and refrain from lending a hand while the other is cooking, washing up, and getting the children off to bed ? Yet this must be the rule for many months to come, and both husband and wife will have to face and accept the fact light-heartedly. The doctor can help to prevent emotional stress by forewarning the couple of this situation in all its details, and so to speak rubbing their noses in it. And there are also the claims of friendships and entertainments outside the home. Many men and women are dependent on their friends and fulfil themselves best in social pleasures. Are these to be abandoned ? Clearly there must be a compromise. Life without visits from friends, occasional movies, or darts at the local may be so depressing as to undermine morale. Besides which, no patient must be allowed to "live for his disease ever after"—a tendency sometimes to be observed in the obsessional type who in pure culture will literally count his steps and order his life with a stopwatch.

Quite often it was nothing out of the ordinary in the patient's circumstances, but rather his attitude towards them—his modus vivendi—which produced his breakdown. This was what happened (we understand) to the writer of one of the two articles on tuberculosis in our Disabilities series.[1] All his life he had shown obsessional tendencies which led him into over-conscientiousness at his work and at his play. Not content with working at his own job during office hours he was always ready to shoulder those of others ; moreover he got into the habit of taking work home with him and utilised the quiet small hours for paper-work instead of sleep. Meals became an unwelcome interruption and represented so many valuable hours wasted in cooking, table-laying, and washing up (for he was equally conscientious at helping his wife in the home) that he did his eating with one eye on the clock. His weekend gardening became a "fatigue," in both senses of the word, instead of a pleasurable recreation. He always had to be getting on with something. Idleness irked him : unless he complied with every condition in Kipling's *If* he could not regard himself as a man. And unfortunately this pathological attitude towards life, with its continual spur of depressing guilt-feelings, is regarded by the world as admirable and something to be encouraged—in other people. The addict also thinks it highly virtuous, and must be taught otherwise. Happily, mere common-sense discussion will usually do much for him, since, like Grosvenor in *Patience*, he is often very ready to change his ways if enough pressure is brought to bear from outside. His duty, of course, is to survive as long as he can as a wage-earner ; and that will not be achieved by flogging himself along in a manner "the like of which he wouldn't treat a horse."

It will be seen that there are few hints and tips of a physical nature for the tuberculous, such as there may be for the one-armed, the arthritic, or the hemiplegic. The tuberculous patient has to *acce* his disability ; which involves reaching a certai attitude of mind. The factors in his life which precip tated or contributed to his breakdown must b altered, as far as is humanly possible, by change job, marriage with the right person, or the adoptio of a quieter mode of living. But if the operative facto cannot be altered, his reaction to them must b changed. More often than not the months which th patient has spent withdrawn into a sanatorium hav wrought a change by the time he leaves. Thing have a way of settling themselves if given tim and for his part the patient has had ample opportuni for introspection, drawing up a spiritual balance-shee and determining his future policy. Should his problem be insoluble it is highly improbable that he wi ever reach convalescence.

Annotations

THE PRENTICE PRACTITIONER

In its report the first Spens Committee showed its *keenly alive to the value of an assistantship in t* training of general practitioners, adding that "even the doctors who intend to become specialists would bene from a year spent as an assistant in general practice." Following the spirit, if not the letter, of the Spe recommendations, the Ministry of Health has p forward *a scheme of grants to practitioners for traini* young assistants. It is proposed that any princi wishing to take an assistant for training shall app for approval to the local medical committee, which to consult two nominees of the neighbouring universi To qualify for a grant the practitioner must have at lea *2000 patients on his list ; he may not increase his l* beyond the maximum that would be permitt if he did not employ an assistant under the schem and he may engage only one assistant at a time in th way. To benefit by a grant (which is restricted to on year) assistants must not previously have been in gener practice in the British Isles except for short periods a locum tenens.

The Ministry suggests that the principal shall recei £150 as a training fee, a sum not exceeding £700 f the assistant's salary and boarding expenses, and a c allowance of up to £150. These financial provisions *not satisfy the Insurance Acts Committee,*[2] which objec that since the maximum number of patients is not t be increased in respect of the assistant in training, is clearly to be regarded as a student rather than a employee (though this was not made clear when th figures first appeared). Yet from the £700—which w be passed on to the assistant, possibly with additions the principal is expected to find the employer's contr bution to National Insurance and superannuatio amounting in all to some £60 ; and the assistant woul still have to pay his own contributions. The Ministry reply is that a trainee should receive less than an exper enced assistant, who, according to current advertisement can expect £700–800 a year ; and both the principal and the assistant's contributions to insurance an superannuation would rank for income-tax allowanc Moreover, advertisements set an assistant's car allowanc at £100, and the proposed maximum of £150 i generous.

This retort does not seem unreasonable. The £100 o so which, by the committee's reckoning, *must com*

[illegible] the practitioner's own pocket or from the training [illegible] has to be set against the probable advantages of ring twelve months' qualified assistance. Similarly, [illegible] young assistant should not resent getting slightly [illegible] than his seniors in similar posts, provided the [illegible] is spent in apprenticeship to a worthy master. bly the number of established practitioners will iderably exceed the number of juniors wishing to il themselves of the scheme. This should ease the l medical committee's task of ensuring that grants [illegible] paid only to principals willing and able to assume [illegible] rôle of tutor; and the presence on the committee university representatives (which has been criticised eedless intervention) may relieve the embarrassment eliminating claimants from a local group.

PSYCHOGENIC RHEUMATISM ?

"It is better to attribute incorrectly a small percentage of organic illnesses to functional causes than to condemn a large number of healthy patients to the fear of a nonexistent disease."[1]

f. Philip Hench, of the Mayo Clinic, speaking on ychogenic rheumatism at the West London *Hospital*, Oct. 12, was much of Dr. Armstrong's opinion. Pains ich the patient calls rheumatic, yet which are not ociated with organic evidence of rheumatism, are fact "body language," he considers—mental pain d anguish experienced as bodily pain. The idea of ychological factor in rheumatism is not new; indeed, denham (as Dr. W. S. C. Copeman recalled) mentioned [illegible] that, were it not for other factors, "might pass a sort of hysteria." The question is whether the se agent, whatever it may be, can ever be left irely out of account. Taking the layman's definition rheumatism as "any ache or pain within half a mile a joint," Professor Hench thinks there are cases in ich it can—cases caused entirely and primarily by [illegible] and frustrations, and often confirmed by injudicious ent ("iatrogenic fixation").

[illegible] rheumatologist can exclude osteo-arthritis and atoid arthritis if their physical signs and radio- ic changes are absent. Fibrositis gives more trouble, [illegible] also has specific characteristics. The patient with sitis tells a plain tale plainly: his pain is a localised [illegible] accompanied by stiffness, causing fatigue, worse the morning and evening and after rest, and affected changes of weather; heat, physiotherapy, and lates relieve it for a time, but it can force its way his attention through any distraction or preoccupation. e patient with psychogenic rheumatism tells a dif- ent story, and tells it in a tense defensive manner: e pain is indescribable, "like" so-and-so, or tingling, ming or stabbing, or it is a strange feeling; it is ten not localised but felt "all over"; fatigue makes worse, but it is often bad all the time, or worse at egular times, not at the ends of the day or related changes of weather, though often associated with otional stress; heat and physiotherapy are quite ely to make it worse, and salicylates are usually effective; he forgets it when his attention is engaged t then he "pays for it later." Thus there are many sitive evidences for a diagnosis of psychogenic rheu- tism; and Professor Hench was able to offer one ore: "when I find myself getting mad at a patient, I know that either I have a migraine coming on, or the atient has psychogenic rheumatism."

Dr. A. Spencer Paterson was unwilling, as a psychiatrist, to accept this massive gift of patients into his ecialty; and put forward the claims of the rheumatic irus. The history, he said, often discloses evidence of rheumatic infection earlier in life—tonsillitis, chorea, or streptococcal infections. It may be that rheumatic infection has rendered these patients unfit for ordinary life, their mental symptoms being a result of rheumatism rather than its cause. The form which neurosis takes in a community is spread by suggestion, and possibly in America the favourite among patients just now is psychogenic rheumatism; but here, whatever may have gone on in Sydenham's day, our duty is still, he thinks, to try to apportion the blame fairly between the rheumatic agent and the trials and errors of the maladjusted victim.

SHEEP STREET

AN advertisement in our issue of Oct. 9 said:

> "As a result of the recent death of a doctor on the Medical List of the Birmingham Executive Council there is a vacancy at 6, Sheep Street, Birmingham, 4, and 80, Great Lister Street, Birmingham, 7, for a doctor who wishes to undertake general medical services. . . . The owners of the properties are prepared to make available to the incoming doctor living and surgery accommodation, and the Council will require the doctor to live at the premises, No. 6, Sheep Street."

Admittedly, at the present time, most doctors entering general practice are glad enough to occupy any existing living and surgery accommodation. But in principle it is surely quite wrong that an executive council should insist that an incoming doctor must live at a stipulated address. The council has every right to require that the doctor shall live and practise near the patients whose care he agrees to accept; but any more precise condition seems hard to defend. However suitable and attractive the house in Sheep Street may be, it should not be made the only possible home for the new doctor. For a thousand and one reasons he may prefer the house next door or the rooms around the corner, and he should be allowed to exercise his reasonable choice.

In these times when traditional relationships in practice have been suddenly uprooted—when doctors are seeking new and non-financial ways of selecting professional colleagues, and ensuring amicable and effective coöperation in the health service—it is essential not to accept rulings that may later restrict our freedom of action, or our width of choice. While recognising that it is well within the competence of any executive council advertising a vacancy to state that it will give preference to a candidate willing to accept certain conditions of service, we cannot feel that it is in the interests of the community or of the profession that a council should lay down so definite a condition as to state the very house the doctor must occupy. In so doing it may incidentally restrict its own choice of applicants to those who allow themselves, by necessity, indolence, or inclination, to be herded to Sheep Street.

B.C.G. FOR NURSES

Dr. J. Heimbeck[1] has brought up to date his study of tuberculosis in nurses at the Ullevaal Hospital since 1924. In the first three years it was shown that the disease developed far more frequently among the Pirquet-negative than among the Pirquet-positive. From 1927 onwards the nurses were classified in three groups according as they were, at the beginning of their nursing careers, (1) Pirquet-positive, (2) Pirquet-negative, or (3) Pirquet-negative and thereupon B.C.G.-vaccinated. Of 501 vaccinated with B.C.G., 49 developed tuberculosis and 5 died of it. This gives 9·8% morbidity and 1% mortality. The Pirquet-negative nurses not vaccinated with B.C.G. showed, however, a 37·3% morbidity and 4·2% mortality from tuberculosis. Since 1932 Dr. Heimbeck has classified his B.C.G.-vaccinated nurses according as they did or did not become Pirquet-positive in response to B.C.G. By 1948 he could show that of 341 nurses rendered Pirquet-positive by B.C.G. only 19 developed tuberculosis, and only 1 died of it, whereas among 115 nurses who remained Pirquet-negative after

of so-called leisure and the tensions caused by the many claims of interpersonal relationships during these hours. For many men and women life begins after the day's work is done. Shortage of help in the home spells a full-time burden for the home-maker. Can either husband or wife bear to lie with the feet up and refrain from lending a hand while the other is cooking, washing up, and getting the children off to bed? Yet this must be the rule for many months to come, and both husband and wife will have to face and accept the fact light-heartedly. The doctor can help to prevent emotional stress by forewarning the couple of this situation in all its details, and so to speak rubbing their noses in it. And there are also the claims of friendships and entertainments outside the home. Many men and women are dependent on their friends and fulfil themselves best in social pleasures. Are these to be abandoned? Clearly there must be a compromise. Life without visits from friends, occasional movies, or darts at the local may be so depressing as to undermine morale. Besides which, no patient must be allowed to "live for his disease ever after"—a tendency sometimes to be observed in the obsessional type who in pure culture will literally count his steps and order his life with a stopwatch.

Quite often it was nothing out of the ordinary in the patient's circumstances, but rather his attitude towards them—his modus vivendi—which produced his breakdown. This was what happened (we understand) to the writer of one of the two articles on tuberculosis in our Disabilities series.[1] All his life he had shown obsessional tendencies which led him into over-conscientiousness at his work and at his play. Not content with working at his own job during office hours he was always ready to shoulder those of others; moreover he got into the habit of taking work home with him and utilised the quiet small hours for paper-work instead of sleep. Meals became an unwelcome interruption and represented so many valuable hours wasted in cooking, table-laying, and washing up (for he was equally conscientious at helping his wife in the home) that he did his eating with one eye on the clock. His weekend gardening became a "fatigue," in both senses of the word, instead of a pleasurable recreation. He always had to be getting on with something. Idleness irked him: unless he complied with every condition in Kipling's *If* he could not regard himself as a man. And unfortunately this pathological attitude towards life, with its continual spur of depressing guilt-feelings, is regarded by the world as admirable and something to be encouraged—in other people. The addict also thinks it highly virtuous, and must be taught otherwise. Happily, mere common-sense discussion will usually do much for him, since, like Grosvenor in *Patience*, he is often very ready to change his ways if enough pressure is brought to bear from outside. His duty, of course, is to survive as long as he can as a wage-earner; and that will not be achieved by flogging himself along in a manner "the like of which he wouldn't treat a horse."

It will be seen that there are few hints and tips of a physical nature for the tuberculous, such as there may be for the one-armed, the arthritic, or the hemiplegic. The tuberculous patient has to *accep* his disability; which involves reaching a certai attitude of mind. The factors in his life which precip tated or contributed to his breakdown must b altered, as far as is humanly possible, by change job, marriage with the right person, or the adoptio of a quieter mode of living. But if the operative facto cannot be altered, his reaction to them must changed. More often than not the months which th patient has spent withdrawn into a sanatorium hav wrought a change by the time he leaves. Thin have a way of settling themselves if given tim and for his part the patient has had ample opportuni for introspection, drawing up a spiritual balance-shee and determining his future policy. Should his problem be insoluble it is highly improbable that he w ever reach convalescence.

Annotations

THE PRENTICE PRACTITIONER

IN its report the first Spens Committee showed its keenly alive to the value of an assistantship in t training of general practitioners, adding that "even th doctors who intend to become specialists would bene from a year spent as an assistant in general practice." Following the spirit, if not the letter, of the Spe recommendations, the Ministry of Health has p forward a scheme of grants to practitioners for traini young assistants. It is proposed that any princi wishing to take an assistant for training shall ap for approval to the local medical committee, which to consult two nominees of the neighbouring universi To qualify for a grant the practitioner must have at le 2000 patients on his list; he may not increase his l beyond the maximum that would be permitt if he did not employ an assistant under the schem and he may engage only one assistant at a time in th way. To benefit by a grant (which is restricted to o year) assistants must not previously have been in gen practice in the British Isles except for short periods a locum tenens.

The Ministry suggests that the principal shall rece £150 as a training fee, a sum not exceeding £700 f the assistant's salary and boarding expenses, and a c allowance of up to £150. These financial provisions not satisfy the Insurance Acts Committee,[2] which obje that since the maximum number of patients is not be increased in respect of the assistant in training, is clearly to be regarded as a student rather than employee (though this was not made clear when t figures first appeared). Yet from the £700—which w be passed on to the assistant, possibly with additions the principal is expected to find the employer's cont bution to National Insurance and superannuatio amounting in all to some £60; and the assistant wou still have to pay his own contributions. The Ministry reply is that a trainee should receive less than an expe enced assistant, who, according to current advertisement can expect £700–800 a year; and both the principal and the assistant's contributions to insurance an superannuation would rank for income-tax allowanc Moreover, advertisements set an assistant's car allowanc at £100, and the proposed maximum of £150 generous.

This retort does not seem unreasonable. The £100 o so which, by the committee's reckoning, must com

[illegible] and pulseless for days and then reduces [illegible] chance by bleeding, and patients with con[illegible] heart-failure, coronary thrombosis, or opium [illegible]. He recalls, too, that a man may show [illegible] signs of a fatal disease without having any [illegible] signs of *impending* death; and indeed, if the [illegible] divests his mind of the thought that the man's [illegible] is incurable, he will find the accepted signs and [illegible] of impending death to be extremely unreliable. [illegible] more, Lord Horder says, about the act of [illegible] than about death itself, and may be hard put [illegible] to say when death actually takes place. He is [illegible] clear about the doctor's duty when it comes to [illegible] dying people die: there is little to be said for a [illegible] who officiously prolongs for his patient the [illegible] dying. Dr. Barber writes with experience of [illegible]surance and support which a good doctor can [illegible] to a dying man and his relatives. Belonging to [illegible] Johnsonian school, he is evasive when the patient [illegible] whether recovery is possible—differing in this from [illegible] Leak, who favours "a quiet straight answer with a [illegible] look in the eye." Since the patient's preference [illegible] this matter is probably a matter of temperament, [illegible] physician will be he who at the moment of [illegible] knows whether to answer as a Barber or a Leak.

Mr. Leak's tactful enthusiasm for embalming has a [illegible] hygienic background, and he reminds us that [illegible] funeral director and his colleagues face some risk to [illegible] in their calling. The body of a tuberculous patient, [illegible] a patient dying of sepsis, may endanger those [illegible] task it is to prepare them for burial, unless tech[illegible] is well designed and careful. The British Institute [illegible] Embalmers has established a research board to inquire [illegible] possible dangers, to the living, from dead bodies; [illegible] funeral directors use their judgment about [illegible] for embalming, regarding the process as a public [illegible] and providing it, when necessary, without regard [illegible] financial status of their clients—a piece of public [illegible] perhaps generally recognised.

ŒSTROGENS IN DIABETES

[illegible] insulin is specific in the treatment of [illegible] there is evidence that some extrapancreatic [illegible] factors may augment its effect and reduce [illegible] insulin requirements. Marcus and Glotzer[1] [illegible] a reduction in the severity of diabetes in post[illegible] patients treated with œstrogenic hormone. [illegible] 7 bedridden subjects chosen, aged 62–77 years, [illegible] had either been present before the menopause [illegible] been aggravated by it. An adequate control [illegible] before treatment is essential, and the diet and [illegible] requirements of these patients were unchanged [illegible] a preliminary observation period of at least five [illegible]. After this, 6000 rat units of œstrogenic hormone [illegible] B') was injected intramuscularly twice [illegible] for three months. A fall in daily insulin require[illegible] of 25–50% was observed in 4 of the patients. There [illegible] also an almost precipitous fall in blood-sugar in [illegible] patients, after four weeks in 5 cases and at the [illegible] week in the remaining one. All the patients [illegible] a "remarkable feeling of well-being," and only [illegible] had uterine bleeding.

[illegible] hormone may exert its effect indirectly [illegible] depressing the secretion of diabetogenic hormone by [illegible] lobe of the pituitary; this view is sup[illegible], for example, by Biro's[2] recent report in these [illegible] of symptoms of hypoglycæmia in patients [illegible] stilbœstrol. However, in previous studies of [illegible] aspects of diabetes, with particular [illegible] to the liver, Biskind and Schreier[3] found [illegible] diabetics not only signs and symptoms of vitamin-B complex deficiency but also syndromes related to excess œstrogen. Intensive nutritional therapy benefited most of these cases, suggesting a correlation between the lesions of nutritional deficiency and impairment of the œstrogen-inactivating mechanism of the liver. These results conflict with the other work mentioned above, but further carefully controlled clinical trials may show, as Marcus and Glotzer hope, that in suitable cases œstrogenic hormone therapy has a place as an adjunct to, or substitute for, insulin.

WAR CASUALTIES

THE Ministry of Pensions' year-by-year account[1] of war casualties, with the varying proportions between the Forces, the Mercantile Marine, and the Civil Defence Services and civilians, reflects in grim outline the actual course of military events. It also reflects a growing sense of obligation to those killed or injured in war. In progressing by short stages it is easy to think that we are hardly moving at all; but by compressing its story of the last nine years into a single report the Ministry shows that step by step we have travelled far from the outlook of 1939. Whereas then the minimum payment to a severely disabled pensioner who had married after being disabled, and had two children, was £1 12s. 6d. it is now £5 11s. Increases derive partly from an improvement in pre-existing allowances, and partly from fresh supplements such as those for unemployability and special hardship. The most notable change of principle in the reckoning is the acknowledgment that a wife married, or children born, after disablement should count for allowances. With increase in their amount, there has been a parallel relaxation in the rules governing the grant of pensions. Thus in 1943 it was laid down that no onus to prove his case should rest on the claimant, who was to have the benefit of any reasonable doubt. Though refusing to accept the principle expressed in the slogan "fit for service, fit for pension," the Government ruled that a Serviceman invalided with a disability not noted on entry to the Forces should receive a certificate of entitlement in the absence of evidence that the disablement was not related to service. This has opened the way to thousands of successful claims which previously would have been rejected.

In these and other changes successive Governments have sometimes led, and at other times followed, national opinion. Wherever the credit may lie, the movement is in the right direction.

THE DISTINCTION AWARDS

THE third Spens Committee recommended that "distinction awards" in three grades should be made to consultants and specialists in recognition of special contributions to medicine, exceptional ability, or any outstanding professional work (other than administrative). These awards, it was suggested, should be made by "a national committee consisting in the main of eminent members of the profession who from their own knowledge or otherwise would be able to reach an authoritative opinion on the comparative merits of candidates." The Ministry of Health last week announced that the Government, in reviewing the Spens report, have decided to set up such a committee, and that its constitution has been settled after consultation with the Royal Colleges and Scottish Royal Corporations. "Invitations to the individual members," it is stated, "will shortly be issued," and a full announcement will be made when the details have been completed.

WE regret to record that Mr. PERCIVAL COLE, consulting surgeon to the Royal Cancer Hospital, London, died on Oct. 19.

B.C.G. vaccination 27 developed tuberculosis and 4 died of it. (There remained 45 nurses not kept under close observation.) Thus a comparison between Pirquet-negative nurses who were not vaccinated and Pirquet-negative nurses whom B.C.G. made Pirquet-positive shows that the tuberculosis morbidity were seven times higher in the former than in the latter.

Heimbeck continues to prefer the Pirquet to the Mantoux test, which in his opinion tends to be too indiscriminately informative. He refers to the possibility of vaccination by the inhalation of B.C.G. in imitation of natural infection with tubercle bacilli; and, being much impressed by the benefits of accidental infection with virulent tubercle bacilli soon after B.C.G. has changed the Pirquet reaction from negative to positive, he looks forward to the time when such accidental infection will be replaced by carefully controlled intentional infection with virulent tubercle bacilli in order that the comparatively short-lived B.C.G. immunity may be replaced or substantiated by a more lasting immunity. His taste for the unorthodox induces a certain breathlessness in some of his colleagues, but the man who twenty years ago was regarded as very dangerous is now honoured as the father of B.C.G. vaccination in Norway.

ASEPTIC DISPENSING

THERE is nothing new in the idea of dispensing by an aseptic technique; for many years systemic injections and some drugs of low stability have been handled in this way. But the advent of penicillin gave fresh impetus to this branch of pharmacy, and nowadays the dispensaries of our larger hospitals regularly supply to the wards sterile solutions not only of penicillin but also of streptomycin, riboflavine, aneurine, ergometrine, water-soluble vitamin K, sex-hormone preparations, and many other drugs. The technique calls for a special laboratory or preparation room similar to that required by the regulations under the Therapeutic Substances Act (T.S.A.). Some of the smaller hospitals are still ill-equipped for this purpose; and the Ministry of Health has lately suggested that in such instances the resources of any nearby pharmacist licensed under the T.S.A. should be employed. The eventual aim must be to supply an aseptic service wherever sufficient demand is manifest. The Pharmaceutical Society, alive to the growing importance of this method, have pressed for the instruction of student pharmacists in bacteriology and aseptic procedures,[1] and today in most of the large towns the schools of pharmacy or technical colleges are holding regular courses in these subjects. In the early days of penicillin the Medical Research Council recommended that the hospital pathologist or bacteriologist should be responsible for its preparation. Now, however, this task is rightly regarded as within the province of the pharmacist. Nevertheless, the pharmacist should not be left to work in isolation. The aim is complete sterility, and the concept of "degrees of sterility" or of "relative sterility" should not be countenanced. The work of retail pharmacists engaged in this field is subject to periodical tests by the T.S.A. inspectors. A few have equipped themselves for actual bacteriological control at all stages; and all deserve any help that local departments of bacteriology can afford.

To some the aseptic dispensary may perhaps seem unduly elaborate, and it may be argued that the doctor's demands for sterile injections could be met from standard preparations. Certainly these are to be had in great diversity, but there remain the unusual dosage or combination, or other individual requirement which cannot be met in this way. Indeed, the increasing need for aseptic dispensing in retail pharmacy is reflected by the growth in the number of T.S.A. licences. Last October the number in England and Wales was 11 now it is 185. The pharmacist in a small way of busin may object to the expense of equipping himself for t work; but comparatively cheap and yet satisfact equipment,[2] and other ingenious devices by which t cost is kept down,[3] have been described.

M.O.H.

THE duties of the medical officer of health are grea altered by the National Health Service Act. Respon bility for local-authority hospitals, which was his, been transferred to the regional board, while the clin services which he administered will be controlled by board or by the local executive council. At first sigh might seem that these changes reduce the interest opportunities of the M.O.H.'s appointment; but at installation, last Thursday, as president of the Soci of Medical Officers of Health, Prof. R. H. Parry stou denied that this is so. "There is little doubt," he "but that in the interest of preventive medicine ma of these changes will be for the better. Much administ tion will be taken from the health department, and consequence the medical officer of health will have m time to devote himself to his professional duties a public-health worker." Henceforth the M.O.H.'s f task is to advise the local health authority on the remo of conditions impairing local well-being. It is not alw easy to combine the functions of administrator advisor, and thus the relief from administrative w should assist him in his advisory duties. Professor Pa proposes that in fulfilling these duties the M.O.H. sho have the help of an advisory committee, whose findi should be made public. The public-health medical off is now at a serious disadvantage in having no opportu to visit the home and the family except as a sanit inspector; and the old idea that he should be "in pendent of private practice" should be discarded. should engage in work as either a private practitione social medicine or as a specialist epidemiologist, in e case with opportunities for research. At the same ti clinicians should be encouraged to interest themsel in public health by gaining direct information abo environmental conditions. The concept of social medici can bring clinician and public-health worker into a team; there will be overlapping, but this is so with good team, for without it a gap is left open. All memb of the team should meet from time to time at case c ferences, in the interests not only of research but the patient. Professor Parry, the declared enemy of t chair-borne, concluded: "Let those that are satisfi sit at the office desk and administer, but for the pioneeri spirit there is still the open road."

OF DYING

Dr. Johnson preferred not to think about death, y when his time came he made a good end. For mo people this is a sound enough policy in dealing wi an event as awkward as it is unpredictable; but docto cannot stand aloof in quite the same fashion. They a obliged to give practical help to the dying, and th must know how best to do it.

In a symposium in the *Practitioner*[4] Lord Hord discusses the signs and symptoms of impending deat Dr. Hugh Barber the act of dying, Dr. W. N. Lea the care of the dying, and Dr. Leslie Banks euthanasia and because dying ends fatally, Prof. Sidney Smit reviews the medical and legal aspects of death, and M G. S. Lear some points about embalming and cremating They read more lively than their subjects would sugge Lord Horder warns against the deceptive patient wh gets better after all—the typhoid patient, who h patterns and sequences, thus clarifying what may be termed their space-time relationship; and from the patterns discerned on examination and the sequences observed over a period of time, the future course of events is predicted. But the original data are considered in the light of further terms—those of physiology, pathology, and ætiology. These are studies by the methods of science; and the gift of insight, the ability to discern and develop analogies, to detect patterns and sequences, and to interpret logically, constitutes artistry that is an integral element in scientific activity at its best.

CONCLUSION

It may be urged, said Dr. Walshe, that this examination of intellectual machinery simply complicates a process normally taken in the stride. Such criticism is more likely to come of intellectual sloth rationalised as practical common sense or from the comforting persuasion that freedom to think implies also freedom not to think, than from any deep conviction that each can do his best without knowing something of how he does it. The capacity to advance knowledge materially and to develop a due critical faculty are both impossible on the plane of practical common sense."

"Further, I ask how medicine can be worthily taught on its academic side unless by minds well versed in the liberal arts . . . understanding the principles on which knowledge is ordered and capable of expounding and of showing in action the reasoning methods involved."

In conclusion Dr. Walshe said:

The need for rebuilding the foundations of medicine was never greater than today when we are being swept along on a spate of new knowledge and new techniques, and have so little time for their due contemplation and integration. Surely there could be no function more truly appertaining to our traditions, or more in harmony with the life of that great natural philosopher whom we commemorate today, than to seek to study and to consolidate these intellectual foundations, and to further what I have called a generality of understanding.

If some philosophy of medicine does not find a home amongst us, where shall this be found? Not, it is increasingly apparent, in the modern university, nor in a Ministry of Health; and if we do not show ourselves eager to promote such a philosophy, then the sum of our corporate activities as a college, whatever their immediate importance, becomes trivialised.

History does not record what book it was that William Harvey was reading, as he sat under a tree with the two young sons of Charles the First at the battle of Edgehill, but we may be sure that it did not deal with consultant services nor with the pay and grading of specialists.

The vigour of such a society as this college can be preserved only for so long as we actively and corporately cherish and foster intellectual ideals. All vigorous societies cherish aims over and above the safe provision of the material necessities and gratifications of their members, and once we allow these to dominate our conscious aims, decadence will have already marked us for its own.

The world in which we live has seen more change since Harvey's day than did the millennium before him. His exhortation "to search and study out the secrets of nature by way of experiment" now has implications he could not have foreseen. Research today within our science is the purpose of large organisations with vast budgets at their command, and its guidance and inspiration have outranged our capacity and slipped from our grasp, for reasons some of which have been beyond our control. Nevertheless, no loyal sons of this ancient college will be willing to allow that we are left without a worthy purpose. This college can, and, if it is to survive as something significant in the intellectual life of medicine, must remain a fountainhead of academic medicine, of true learning—the home wherein a philosophy of medicine finds a permanent abiding place and disciples eager to learn and to teach it, and where the liberal traditions of medicine can look confidently for their defence against the constant threat of debasement by the technical arts and by the spiritually and intellectually oppressive materialist dogmas of our day.

THE TRANSVAAL HOSPITALS DISPUTE

FROM A SOUTH AFRICAN CORRESPONDENT

MANY of the arguments lately heard in Great Britain have been aired again in the Transvaal province of South Africa, where doctors are involved in a dispute with the Administration over the proposed introduction of a free hospital service. So definite and irreconcilable are the opinions of the disputants that honorary staffs in the hospitals of the province have refused to operate the proposed scheme, and consequently the hospital service is disrupted and is deteriorating rapidly.

Hospitals had for many years been financed and organised out of public funds, but had been staffed on the "voluntary" plan with interns and honorary surgeons and consultants. As a new measure of social service a recent ordinance of the Transvaal Provincial Council proposed that all hospital treatment should be completely free, and to this end new salaried posts should be created in the hospitals, which it was hoped that the present honoraries would apply for and accept. The South African Medical Association felt that a completely free service was not desirable, and suggested that a means test should be applied. This suggestion met with no sympathy from the Transvaal Provincial Council, which maintained that the ordinance expressed the will of the people.

Both sides made emphatic public statements. The S.A.M.A. maintained that the new ordinance would bring about increased demand on the hospitals and hence lack of accommodation for the adequate treatment of the sick poor; that it would endanger the livelihood of the profession; and that by allowing free medical treatment to those who could afford to pay it would upset the whole foundation of the honorary system. The Administration replied that a system of hospital care paid for by taxation would remove the dread of financial embarrassment that serious sickness means for the middle-class patient; that there would always be enough remunerative work for doctors even under the new system; and that the authorities were fully prepared to pay for medical services rendered under the ordinance.

The dispute dragged on. On Oct. 1 the new ordinance came into force. The doctors did not apply for the new salaried posts, but proposed attending inpatients in the hospitals for a further fortnight as a period of grace. They also proposed mediation, which the Administration would not accept. On Oct. 2, when negotiations seemed to have broken down, the S.A.M.A. issued a directive that all honoraries should cease acting immediately, provided that, if they were permitted access to the hospitals, they should continue treating patients admitted before Oct. 1, and that emergency cases should be treated if specially requested by the medical superintendent. At the same time the S.A.M.A. reiterated its previous demands, and the Administration repeated that it could not accept these demands.

While this action was designed to safeguard at the same time the patients' interests and the doctors' rights, it inevitably curtailed the hospital services and largely shocked public opinion. In most hospitals emergency arrangements were made with the staff available. Outpatient departments were generally closed and bewildered "regulars" were turned away. Casualty departments functioned, but patients requiring ward treatment were put on a waiting-list. As patients left hospital and very few new ones were admitted, beds and wards rapidly emptied. The Transvaal newspapers published photographs of operating-theatres standing unused, and there was much mention in the press of the Hippocratic oath.

The Transvaal Provincial Council then announced its intention to take a referendum, asking the public to

Special Articles

THE STRUCTURE OF MEDICINE

DR. WALSHE'S HARVEIAN ORATION

The annual Harveian Oration was delivered at the Royal College of Physicians last Monday, St. Luke's day, by Dr. F. M. R. WALSHE, F.R.S., who took as his subject the Structure of Medicine and its Place among the Sciences.

Commonly, he said, the intellectual structure of medicine is expounded in terms of two pairs of antitheses—namely, art and science, observation and experiment. Thus the relative scope and limitations of observation and experiment are treated, not as they should be, in terms of experiment as one mode of observation, but as though the two terms expressed a thorough-going dualism in scientific method. A comparable distortion usually informs the comparative consideration of the rôles of art and science, and many an empty argument has been held on whether medicine is the one or the other. In fact, all these antitheses arise from the unguarded use of abstraction. To achieve a philosophy of medicine it is necessary to escape from the fragmentation of ideas that comes of thinking too exclusively in the *static* terms of classifications; more thought should be given to the idea of process.

MEDICINE AND PHYSIOLOGY

Some physiologists, said Dr. Walshe, would deny medicine its place among the sciences, and speak of it as nothing more than applied physiology. Historically, such a claim is easily refuted, for the hospital is the cultural ancestor of the laboratory, and experimental physiology was born of therapy. Implicit in the physiologist's argument is the thought that medicine does not carry its analysis of phenomena back to fundamental notions, but stops at a half-way house where it meets and tends increasingly to borrow from other sciences. Yet here medicine is no exception amongst the biological sciences; and indeed physiology has been eagerly borrowing from the other sciences for the past hundred years. The truth is surely that every successive layer of thought in the analysis of nature, living and dead, stops at a half-way house when tracing its ideas back to their basic elements, and is content with ideas of a generality sufficient for its immediate purpose. For philosophy alone, which aims at supreme generality, there is no half-way house.

Some generality of understanding is the essence of a civilised culture; the medical professions must seek it if they are not to decline to the level of craftsmen and technicians. This danger is real; and the many proposals for reform of medical education designed to avert it have been superficial and uncoördinated.

OBSERVATION AND EXPERIMENT

In observation, Dr. Walshe continued, what is retained is retained in a subjective order of importance, and thus there is some distortion of the impartial facts. The term "trained observer" acknowledges that observation is discrimination and not a product of pure sense perception. All observations are subject to interpretation in terms of concepts; the notion of pure knowledge as the product of pure sense perception corresponds to nothing in human experience. There is a constant interplay between the conceptual and the observational order of experience. New observations modify concepts; but, not less, new concepts lead to fresh possibilities of observation. The mind that observes is also the same that devises, performs, and interprets experimental observations; for experiment is but a method of providing observable data. Thus no higher order of rationality attaches to experimental observation.

In medicine, the data, often very incomplete, a taken in all states of refinement. They have to be sort translated into the language of medicine, expanded analogy, logically interpreted, and finally made to emer as clearly formulated propositions, and as exemplifi tions of laws of nature. It is because important data so often lacking that recourse is commonly had to method of experiment. The ultimate aim of the scient observer is to grasp the principles inherent in the stre of evanescent phenomena; and by experiment he se to isolate his material to make it reveal its principl In the words of A. N. Whitehead, "experiment is a w of cooking the facts for the sake of exemplifying law." Experiment thus provides a double clarificatio the formulation of an abstract principle, and the exe plification of it in as simple and unequivocal a medi as possible. Clearly an even higher degree of abstracti is involved here than in simple observation. This perhaps why the experimental method, exclusiv pursued, may prove narrowing to the mind; it may a account in a measure for the ill-disguised hostility many experimental scientists to metaphysics. "Act is easier than contemplation." Nevertheless, fundamental distinction separates observation experiment. In both there is a concentration attention upon specific phenomena, and also so control of events; and both seek to provide data interpretation.

In medicine there is too great a readiness to equ the notion embodied in the word "experiment" w that of "animal experiment," and to think of exp ment as something divorced from the bedside. Sim experiments are prevalent in day-to-day clin studies.

> "Every time we evoke an extensor plantar response every time we elicit a knee-jerk, we are forcing cert spinal mechanisms by their mode of reaction to re internal conditions in the central nervous system unaided observation by the five senses cannot tell us. We are controlling conditions and isolating our mate by a method that has all the essential form of the expe mental method. . . . The hospital ward is a laborato in the fullest sense, is indeed the parent of all biologi laboratories."

ART AND SCIENCE IN MEDICINE

In discussion of art and science in medicine some le too readily to hard antithesis, for the continual tenden is for the practical arts to be converted into appli science. In theory this is understandable, for the practic arts are operations according to rule, and rules are gene propositions referring to particular cases and direct *to future situations.* Thus the rules of a practical art predictions to be tested and validated by prescrib procedures. In this may be seen the slow developme of science in medicine—the emergence of ideas fro activities, and the influence of these ideas in rationalisi and modifying the activities from which they emerg As to the term "applied science," it is well to rememb that this cannot be applied in medicine to the fruits scientific discovery irrationally employed.

Turning to the intellectual arts, Dr. Walshe said th here the problem becomes not that of art *and* scien but that of art *in* science. The physician seeking to b scientific attempts to transform the confused data direct experience into the clearly formulated proposition of a *rational* science, and to identify the patient' situation as a particular example of the *relevant* natura laws or general principles. The accomplishment of th is essentially a special example of the use of the libera arts. "For the trained mind every complex of presentin phenomena is a text to be read, translated into th grammar of science, rhetorically expanded, and logically interpreted." Signs and symptoms are grouped int

Disabilities

15. DEAFNESS

The general public does not understand deafness. Partly I surmise because it attracts little attention and does not evoke sympathy to the extent that blindness does. The reaction of most people when told that I am deaf is to shout in my ear; and on being told that this is useless, that I lip-read with great difficulty or not at all, and would they please write their question down on paper, they walk off. Nor is it appreciated that hardly two cases of deafness are alike. Each has its peculiarities. There is every grade of deafness from very slight to complete, and these grades are further differentiated by whether the deafness be from birth, early childhood, later childhood, adolescence, maturity, or old age. On top of this is the mental capacity of the deaf person and his attitude to life; this last is more important than anything in determining whether deafness is to be an insuperable obstacle or not.

I became totally deaf in 1915 as the result of cerebrospinal meningitis, when I was 13. I believe I had exceptionally sensitive hearing before that, for I could pick out with ease the various voices singing in harmony, and too close a proximity to fireworks would temporarily deafen me. For two days I was delirious, and my first impression on waking was that the large building opposite my bedroom had been transformed into a war factory, for I could hear machines buzzing, hammers forging metal on metal, and steam escaping from valves. I was speedily undeceived by my mother writing to me on a slate, for she had already discovered that I was deaf.

The noises I heard were, of course, tinnitus, and they have persisted ever since; so it is erroneous in my case to describe myself as living in absolute silence. On the contrary, a bigger medley of sounds than I can describe accompany me willy nilly, though I have long since learnt to ignore them when my mind is otherwise occupied. Submitting to the fact of total deafness, as I must, I am rather glad than sorry that I have these head-noises, for I find it pleasurable at times, and even profitable in a sense, to bend them into a tune remembered from my hearing days or composed impromptu. The various sounds accurately fit instrumental music. In this purely subjective manner I can "hear" music at times; perhaps Beethoven, who was for years stone deaf, composed in this way!

Almost complete loss of balance accompanied the onset of my deafness. It took me fully six months to learn to walk reasonably straight in daylight; and only by walking swiftly could I keep a fairly straight course in the dark, and then only by having something visible—a lamp or a lighted window—to steer by. A turn of the head to speak to a companion would upset my balance and make me wobble about like a drunken man. Even now, I cannot walk straight in complete darkness.

A further peculiarity was (and is) that whereas before my deafness my field of sight remained at a constant level, it now went up and down with the movements of my head. At first this was a nuisance, but it has become somewhat modified with the passing of the years, though it is still noticeable when the head is involuntarily jerked as in vehicles passing over bumpy roads.

These were the subjective results of total deafness in my case; but they were not the most important effects. It was at once forced on me that deafness means isolation from the normal world. It was uncanny after about three months in and out of various hospitals and convalescent homes to revisit the scenes of my recent hearing life, to meet my former class-mates, to watch the heavy streams of traffic in the West End, and yet to hear absolutely nothing. Vibration could be, and still is, felt; but only from heavy vehicles, or from footsteps on wooden floors.

Being cut off from one's fellows by an invisible and ever-present barrier is the heaviest blow and disability of deafness. My friends knew nothing about it; only personal contact with me could have taught them, and that personal contact I dreaded. There was a constant tendency to withdraw as far as possible from intercourse with the outside world, and obviously if this had been allowed to go on unchecked mental instability would have resulted. Even so, my speech began to suffer through lack of use. I became more and more tongue-tied, and when I did speak I gabbled. Normal folk had difficulty in understanding what I said.

I can hear my own voice perfectly—even a whisper sounds loud—but I know that to hearers my voice has the characteristic deaf tone. I can also sense a difference in my voice according to the size of the building in which I am speaking; but whether this is based on reminiscence or not I cannot say.

* * *

Such then were the general conditions with which I, at the age of 13, had to face life. At first I was somewhat buoyed up by the repeated statement that in time my hearing would return. It did not, and I am now aware that deafness resulting from meningitis is virtually for life. Six months later I went to a deaf school, and at about the same time I entered what is known as the "deaf world" by joining in the activities of the Royal Association in Aid of the Deaf and Dumb—otherwise I might well be mentally ill today.

Though I had become totally deaf so young, I had one great advantage over the born-deaf and those who become deaf even earlier than myself—I could read with profit. On that apparently simple fact, coupled with my entry into the "deaf world" everything hinged. It was a cardinal point. At the deaf school I simply could not lip-read. The ability to lip-read is a gift. You are either born with it or you are not. Out of the hundreds on hundreds of deaf people whom I have met, very few can be called genuine lip-readers, and I know no lip-reader at all who can follow a normal speaker at a lecture. Those without the gift can try for years and never get beyond mastering the ordinary phrases "How are you," &c. But I could read.

It was clear that I should have to educate myself solely from the printed word. There is a saying: "The eye for the ear, and the hand for the tongue"; and it illustrates the truth that for the deaf all knowledge must go in through the eye, and much of it must be spoken on the hands by using the manual alphabet or by signs. My communication with the non-deaf world is almost entirely by means of pencil and paper. If my school-teachers wished to tell me anything they had to do it in writing, for some refused to spell on their hands. If my employer wished to give instructions he too had to put it on paper; I found this rather an advantage, for if any mistakes were made I could verify what I had been told to do. I cannot say that I found total deafness a disadvantage as a silversmith. On the contrary, the fact that I could work at a delicate job amidst terrific dins was a great help, and I took full advantage of it.

Meanwhile for a decade I had been living in the deaf world. Nearly all my former hearing friends had long since dropped out of my life; but in their place I had made contacts with deaf ones, and was taking part in a normal social life with them. In this way my own deafness became, as it were, normal.

I suppose I am one of the few totally deaf men to have been through a college. I was allowed by the authorities at King's College, London, to take their theological diploma. The same could be done by any deaf person provided they can read with profit. I attended lectures, decide whether a means test should be applied to the hospital scheme or not. There seems to be some doubt as to the legality of this step—which is unprecedented in the Union—and the council have since deferred action, while again discussing the possibility of the appointment of a mediator acceptable to both parties. Whether either side is now prepared to accept—by referendum or mediation—a solution contrary to its own proposition is somewhat doubtful.

Johannesburg interns have stated that they cannot carry on with work outside the range of their experience without the guidance of the honorary staff. In this statement they have since been supported by the interns of other hospitals in the Province. So the dispute goes on with statement, ultimatum, and counter-statement.

POLIOMYELITIS IN NEW ZEALAND

FROM A NEW ZEALAND CORRESPONDENT

In New Zealand the conduct of operations against serious epidemics is on national lines instead of being left in the hands of the medical officer of health according to the needs of the district. And mass restrictions have always been more popular in the Antipodes than in Britain. So when poliomyelitis descended suddenly on Auckland last November, producing 26 cases within a fortnight, a ban was placed on all gatherings of children under sixteen throughout the Dominion, and on their travel between the two islands. The interference with education, and the dislocation of normal community life at Christmas, were serious, and by March it was obvious that the bans were no longer serving any useful purpose even if they had originally done so. Accordingly the official policy was changed in favour of closure of the particular school affected. By this time the epidemic was running at some 13 cases a week, and it has since continued throughout the winter, with seldom less than 20 cases a week and with the Auckland province still providing the highest incidence.

The Wellington health district has never been immune, but there were not very many cases till recently when the disease showed evidence of rapid spread, attaining 72 notifications in September. The reopening of the schools was therefore postponed. But the Royal Australasian College of Physicians, meeting in Dunedin, passed a resolution for the consideration of the minister of health that "there is convincing evidence from epidemics elsewhere that the general closure of schools has had no influence on the spread of the disease or its severity," and "at this stage of the epidemic no useful purpose can be served by the general closure of schools," adducing as evidence of this the very high rate of abortive cases among both adults and children. The minister accordingly announced a new approach to the problem. Children were to wash their hands before eating, parents were to provide them with towels, and teachers were to see that excessive fatigue was avoided, to wage war on flies, and to conduct a morning health inspection, reporting any suspicious symptoms to the district health office.

Now the newspapers have just described a report by Dr. A. W. S. Thompson, medical officer of health at Auckland, tabled in the House of Representatives as an appendix to the annual report of the department of health. He and his colleagues investigated fifteen areas, each of about twenty houses, where the first cases of poliomyelitis occurred, and noted the incidence of minor illnesses consistent with a diagnosis of abortive poliomyelitis. (For purposes of comparison a similar inquiry was made in areas on the other side of the harbour where no cases had been notified.) The ratio of suspect illnesses to positive cases proved to be about 300 to 1, and on this basis the true number of cases in t Auckland outbreak has been about 40,000 in ni months.

REFRESHER COURSES FOR GENERAL PRACTITIONERS

MINISTRY'S ARRANGEMENTS

The Ministry of Health has set out in a memorand (G.P.R.C.1) the Government's scheme for grants und the National Health Service Act to practitioners in t National Health Service who attend refresher cours The memorandum also defines the conditions on whi doctors engaged in general practice before recruitme to the Forces may apply for a similar grant aft demobilisation.

Practitioners in the Health Service.—The courses f attendance at which financial assistance is offered a those specially arranged for general practitioners by t universities and medical schools. A practitioner taki part in the N.H.S. can claim grant for attending o course of 22 half-day sessions or two of 11 half-d sessions (which may be either intensive or spread o a number of weeks), provided that:

1. He has been qualified for at least three years.

2. He has not less than 500 (or in a rural practice 2 people on his list. In the early days of the service, howev a minimum of 300 (or 150 in a rural area) may qualify.

3. Within the previous year he has not received financ assistance under the Government schemes for doctors releas from the Forces, or for N.H.I. or N.H.S. doctors. Exceptiona this condition may be waived.

Application for admission to a course and for gra should be made on form G.P.R.C.2 to the universit which, if prepared to accept the applicant, will forwa the application for grant to the Ministry. The Minist will then inform the doctor, the executive council, an the university whether the application is approved. doctor qualifying for grant is normally not concerne with payment of the course fees. The following expense may be reclaimed by those qualifying: (1) subsistenc allowance up to £1 a day, if attendance necessarily entail absence from home at night, or otherwise actual expense up to 5*s.* a day; (2) travelling expenses; and (3) pay ment of a locum tenens where necessary, up to a maximu of 14 guineas a week.

Details are given in the form of claim (G.P.R.C.3 which should be completed at the end of the course an sent to the postgraduate dean or director who, afte certifying that the course had been attended, will forwar it to the Ministry for settlement. Copies of applicatio and claim forms are obtainable from postgradua deans or directors.

Ex-Service Practitioners.—Broadly the arrangement for practitioners released from the Forces are the sam as those for doctors in the N.H.S. Ex-Service doctors are, however, given the option of returning to thei medical school, where they may select the instructio they most need; and in this event they can claim reimbursement of fees up to a maximum of 10 guineas for 22 sessions. The conditions on which grant is made to the ex-Service practitioner are that:

1. He applies within a year of demobilisation.

2. He has not within the previous year received financial assistance under the Government schemes for doctors released from the Forces, or for N.H.I. or N.H.S. doctors. Exceptionally this condition may be waived.

Any ex-Service practitioner satisfying these conditions, and accepted by the university, automatically qualifies for grant; the Ministry's prior approval i not required.

Letters to the Editor

M.R.C.P. EXAMINATION

SIR,—“Another M.R.C.P.” remarked very truly on Sept. 18 that what is wrong with the membership examination just now is “not the system but the excessive number of candidates.” He makes three good practical suggestions for deterring “sportsmen from putting a bit on the membership as if it were a horse”; but, like other correspondents. he does not inquire into the reason for this recent embarrassing increase in the number of young medical sportsmen. No doubt there is more than one cause or motive, but I am quite sure the increase derives mainly not from an outburst of sportsmanship, a sudden lust for learning, or desire for a crown of wild olive. but from the flight from general practice, easily predictable at the time of the white-paper and now plainly visible to all not wilfully blind.

The young man sees, looming close ahead, a statutory definition of consultants and specialists which, for physicians. will include the membership. He sees the existing ditch which splits the practising profession being industriously deepened and widened, its banks heightened and concreted. the bridges over it destroyed and no new ones built or even planned. Beyond it he discerns the Accredited Consultants. to whom shall belong whatever of honour, glory, power, and dominion the profession may enjoy, substantial salaries, at least some freedom to define their own fields of activity, that protection from exploitation which belongs to institutional practice, and at least some proportion between reward—financial or other—and quality of work. On his side he sees “the rest,” general practitioners rather by inference than definition, the Universal Providers, the indispensable but unhonoured middlemen, the unlockers (on request) of the medical toy and sweet cupboards, defenceless against exploitation from below or regulation from above, shut out from the hospitals and unsupplied with ancillary services, remunerated quite without regard to quality of work, qualifications or proved ability. This is the “set-up” for the future the young man sees. accepted by Parliament. disliked but not rejected by his profession, seemingly intended to be permanent. I suggest that unless widening operations on the dividing ditch are called off. bridges constructed without delay, and conditions of professional life and rewards for good work on the near side brought up to those on the far, the pressure of unlikely candidates on the membership and fellowship examinations will be the least of the evils we may expect to fall on medicine. on our profession, and, of course. on the public. who still do not understand that what is bad for medicine and the profession must be bad for them.

London, N.W.3. LINDSEY W. BATTEN.

INFANTILE GASTRO-ENTERITIS TREATED WITH STREPTOMYCIN BY MOUTH

SIR,—It is encouraging that Dr. James and her colleagues (Oct. 9, p. 555) have found streptomycin to be an effective drug in the treatment of infantile gastro-enteritis, but it is profoundly disappointing that they have not reported an effectively controlled experiment on a large number of cases. Gastro-enteritis. of all conditions, is one in which the severity and the mortality varies in different individuals, different countries, towns, and hospitals, and in the same hospital in different years, so that in one epidemic no deaths may ensue while in another a third or more of the affected babies may die.

This paper reports the results with streptomycin in three groups of cases. In group A, 4 newborn infants received the drug and are compared with 23 cases treated by “routine measures.” There were no deaths and it is claimed that following streptomycin the 4 treated cases, though “the most severe in the outbreak,” recovered more rapidly than the 23 untreated. In group B—12 infants in a residential nursery—4 cases, including 3 which were “much more severely ill than any of the controls,” received streptomycin some days after diarrhoea had commenced, while 8 had no streptomycin. Again there were no deaths and again it is claimed that response to streptomycin was rapid. The way in which the authors not to listen, for I couldn't, but to copy notes from friends as I sat beside them. In that way, and by borrowing other notes, I probably obtained a better record of a lecture than the normal student. The notes, coupled with the careful study of recommended books, enabled me to hold my own. After all, this is much the same as taking an external degree. For many years now I have been employed as a chaplain and worker for the deaf, and have met thousands of all types. Our classification is generally this: the born deaf, or the deaf and dumb; the deafened, those who suffer from more or less severe acquired deafness; and the hard-of-hearing, who with an aid can retain their place in the normal hearing world.

For the first two classes the greatest disability caused by deafness is the isolation and cutting-off that I have described. The disability of having been born deaf, though it has the inevitable consequence of retarding education to a degree quite unrealised by the public, is less of an affliction than acquired deafness, for the born deaf never know what they miss.

Where deafness is incurable, either from birth or afterwards, the only way to a normal life where the disabilities of deafness can be forgotten is to take an active part in the social life offered by the welfare agencies. In spite of the many things that a deaf person can do as well as the normal, deafness remains a formidable handicap. The Disabled Persons Act and the new National Assistance Act may do much for the likes of me. A regular job, freedom from anxiety, and an interesting social life are needed if the results of deafness are to be side-tracked.

Public Health

Mobile Maternity Centres

THE Ministry of Health, in a circular (161/48) to local health authorities, suggests the use of specially equipped vehicles for the examination of mothers and young children in remote areas. These mobile centres could be used as adjuncts to waiting-rooms hired periodically, or for conveying the equipment needed to convert rooms temporarily into a maternity and child-welfare centre. The Minister also urges the formation of further mobile dental clinics.

Poliomyelitis in the U.S.A.

The poliomyelitis epidemic in the U.S.A. is now believed to be past its peak. In the week ended Sept. 25 the number of cases reported was 1609, compared with 1840 in the previous week. The five-year average for the corresponding week is 881; and in 1946, the last big epidemic year, there were only 1425 cases. The decline, says *B.U.P.*, has come later this year than in 1946, and the cumulative total of cases for the year up to Sept. 25 is higher—17,653, compared with 17,206 in that year. Between March 20 and July 24, 59% of all cases were recorded in North Carolina, Texas, and California; the present fall is sharpest in the north central States.

The Second Quarter

The following vital statistics have been reported for the second quarter of this year:

—	Births		Deaths		Infant mortality per 1000 births
	No.	Annual rate per 1000	No.	Annual rate per 1000	
England and Wales	203,711	19·0	110,356	10·3	31
Scotland	26,554	20·7	14,695	11·4	43
Northern Ireland ..	8030	23·9	3821	11·4	44
Eire	18,006	23·8	9419	12·5	46

In England Now

A Running Commentary by Peripatetic Correspondent

IN the course of several years of psychiatric practi I have regarded the term "trick-cyclist" at first wi suspicion, later with tolerance, and finally with affectio It is a kinder appellative than many that come our way it at least suggests that one is capable of performanc requiring unusual balance and poise. It came, howeve as something of a trauma to be confronted with t real article, a being who literally trick-cycles for h bread and butter. Referred by his M.O. as a case anxiety state, Sydney was a tremulous sweaty weed a youth who laid claims to "blackouts" for as long as could remember, if not longer. He had always been t shy to play with other boys, and his dad had boug him a motor bike "to bring him out of himself." T desired social effect was apparently not forthcomin and dad, perhaps in despair, had gone off with The Oth Woman. Having now a mum as well as a motor bi to care for, young Sydney very creditably sought mo gainful employment. Came the local fair and our he found himself gazing at the "Wall of Death" with a w surmise. Modestly he offered to reinforce the small staff two, the Boss and the Lady. Surprisingly he was accepte

At that time he was averaging three blackouts a da but for several weeks he contrived to have them lavatories, peep-shows, pubs, and secluded gutters, a to keep his art pure and uncomplicated. It took him b five minutes to learn that his trade really amounted no more than a steady 20 m.p.h. jog, the impression spectacular speed being contributed by the small circu ference of the wall, and the incredible horizontality the whole affair resting entirely with that mysterio but ubiquitous agency, centrifugal force. He was pe mitted to graduate to steering with his feet on t handlebars; but the Lady's tour-de-force of standing the saddle was strictly copyright.

Inevitably, however, he was discovered blacked-out a prostrate, and was summarily dispensed with as bei liable to make the wall altogether too deathlike. Sub quently conscripted, he was classified as unsuitable f dispatch-riding, much to his dismay. As a mess order he was obliged to remain vertical for as much as hour at a time. Accordingly he showed an increasin tendency to regress to a horizontal, though unconsciou similitude of his earlier state.

I wonder if they call trick-cyclists "psychiatris nowadays?

* * *

A visit to the Jackson Laboratory for the Study Animal Behaviour, Genetics, and Cancer, at Bar Harbou Maine, confirms one's belief in the phœnix. Last ye some careless workmen left an incinerator fire before was properly extinguished, and it spread into the pe soil, eventually defying for ten days the efforts thousands of people and a score of fire brigades. Th main building was in the centre of the conflagration an was burned out, and nearly all the mice inside wer burnt or suffocated by smoke. The visitor now see an untidy sort of compound, or barrack square, with few poles and triangles embedded in it, surrounded b the charred stumps of felled trees. At one corner stand the one remaining wing, which was fireproof, cover with wooden scaffolding (this is pine-tree country) with a new roof being finished, and adjoining it a nev wing, now almost complete. At the other side of th square there are three large wooden bungalows which house the summer school. For this there is an enrol ment of some thirty students, who range from college freshmen to candidates for master's degrees. In addition, a dozen or so summer investigators of PH.D. status come up for a few months to work with the incomparable material of the Jackson Laboratory or to escape the heat of the cities farther south and write in peace and quiet. The stakes and triangles are the real skeleton of the phœnix. The new building, when it is completed next year, will have an auditorium, a library, offices, a histology and a biochemistry laboratory, and an electron-microscope room. The old section will only house the mice, which are already back in their thousands. Nearly all the known genes have been reassembled from all over the world.

scale processes used in the production of pharmaceuticals which have made it impossible for the pharmacist to dispense, extemporaneously, all the preparations which modern research has placed at the doctor's disposal. This, of course, applies to the ethical proprietary. With the domestic proprietary the work of the Chemists' Federation has made it possible to envisage the integration of all the pharmacist's activities, since his professional interest in, and understanding of all C.F. proprietary preparations has been justified.

Suggested Principles in Evolving Controls.—Since voluntary control is far healthier and far less expensive, both in money and personnel, than statutory controls, the latter should be kept to a minimum. To encourage success and enterprise the State should be prepared to offer appropriate rewards. Is not the inclusion of the list of substituted proprietary preparations in the *N.W.F.* directly opposed to such a principle? The medical practitioner should be free to prescribe what he believes to be medically necessary for his patient, so that the initial responsibility for deciding what drugs are necessary is placed where it rightly belongs—in the doctor's hands. This principle has been subscribed to by the Minister, though it remains to be seen how far it [illegible] be applied to proprietary medicines.

The medical profession has been well, and often brilliantly, served by the pharmaceutical industry—a contribution to the health and prosperity of the nation which a narrow or shortsighted policy can destroy.

London, N.W.10. E. W. GODDING.

MEDICAL SECRETARIES

SIR,—May a woman have the last word on this subject? As a medical secretary myself, I should like to uphold the claim for special training of medical clerical workers. If I had wanted to take up nursing, physiotherapy, social service, or any other work connected with a hospital, I should certainly not have been accepted without suitable preliminary training; yet I came to my job from one of the Services (and before that a commercial office) with the haziest knowledge of medical terms and hospital procedure. For the first week or so I was in despair, and probably the medical staff weren't too happy either. Having, fortunately, a good memory for words, I worried through and now wouldn't change my job for anything. But every day makes me realise what a lot of technical words I *don't* know. I should welcome a training course which would give me something of the general groundwork of a nurse's training.

Medical secretaries believe that their status would be raised if inducements were offered to young girls to make this a career. With my seniors, housemen, and consultants to type for, and my clinics, waiting-lists, card indexes, two telephones, and other time-occupiers, I don't feel I work any less hard than my colleagues in the technical sections: and I should like to feel that we will eventually reach their rate of pay and length of holidays. Bearing in mind the number of hospitals and doctors needing clerical help, is it too much to ask for specialised training for youngsters who would "love to work for a doctor," but get panicky *if asked to spell* "appendicitis"?

DOCTORS' SECRETARY.

ANOMALY OF ABDOMINAL MUSCULATURE

SIR,—An unusual anatomical anomaly was found in a man who lately came to me for removal of a vesical pouch. The patient was aged 69. The abdominal wall was apparently healthy, and the bladder, which had a pouch the size of a billiards ball, was approached by a transverse [illegible] through the aponeurosis overlying the rectus. Instead of the vertical disposition of the muscle beneath the sheath, I found subjacent fleshy fibres passing horizontally to the linea alba. Although momentarily stunned by this, to me, unique anomaly, I quickly realised that, instead of becoming aponeurotic at the linea semilunaris, the flesh of the internal oblique had continued over the face of the rectus abdominis. The right rectus appeared average, but the left some 40% below average.

This variant had apparently not impaired the efficiency of the parietes. The wound healed normally.

[illegible] A. WILFRID ADAMS.

UNDER TENSION

SIR.—*Among all the sorts* that read THE LANCET there will be those who disapproved of your leader of Oct. 9, and those who approved of it. I should regret that only the former should be represented in your correspondence columns. To others of us your sober reflections round the theme that "it takes all sorts to make a world" contain something more than a half-truth when we are faced with Dr. Chapman's alternative—to look at one half of the world as one who "repeatedly attempts to destroy him and who proclaims, fortissimo, his intention of going on trying. . . ." We seem to glimmer Dr. Chapman's logical counter to that one.

We are clearly enough in a dangerous situation. Dr. Chapman has heard voices and he isn't the only one. Are those voices real? Are they by any chance also heard in Russia? There is always something of fact for international paranoia to batten on. But how little relative to the issues of sane settlement! And, taking the long view (say 40 years in this case), how fundamentally equal are the intolerances and the provocations of the opposing sides! Are threats to vital interests (implied or felt) ever limited to one side in a major international dispute?

It may one day become clearer that the threat which 1948 offered to our world was not primarily that the policy of any power-group aimed at the destruction of the vital interests of any other power-group, but that everywhere people *came to think this so.* Some individuals and some peoples may have more of suspicion to unlearn than others; some undoubtedly have more to unlearn of cruelty to their foes. But shall that thwart our peaceful solution? Such complaints are perennial. Grotius, a Dutchman, tried to set up international law in 1625 but decided that one couldn't cope with the Portuguese.

What we lack is scientific machinery for settling international disputes despite the froth of irresponsible journalism and the honest prejudice of so many men and women. What more appropriate, then, to THE LANCET's last than that it should chase the mental health of peoples a little further than did our recent international congress by reminding us where we stand today? To secure world order, international legal machinery has to be made just as calm, dispassionate, and secure as our own domestic courts of law—simply because it takes all sorts to make a world and (may I add?), because to err is human.

Edinburgh. RANYARD WEST.

HOW MANY NURSES?

SIR,—Dr. Cohen takes as the criterion of nursing and medical effectiveness in hospital the patient's duration of stay "which is assumed to be an index of his duration of sickness." *Is* this assumed by anyone who stops to examine and consider the factors governing admissions to and discharges from hospital?

It is possible that duration of sickness might be accepted as one criterion (among several) of effective care, but it is surely very dangerous to single out that chapter in any individual's ill health which he is allowed or persuaded to spend in hospital, and which may occur at an early or a late stage of his illness, as the index of the duration of sickness. One hopes that at present the hospitals, hard-pressed though they are by waiting-lists, take into consideration the home circumstances of the patients before deciding at what stage of invalidism or of recovery they may safely be allowed to leave. I know that this is an important factor to the good ward sister, whether surgical, medical, or obstetric. To take the simplest instance, has the anxious primipara sent out on the 8th day to a comfortless home (where she immediately "loses her milk" and learns by failure) really received more effective care than the one who goes out on the 14th day or later with a little additional confidence, stability, and knowledge of her new responsibilities? The same applies in the fields of surgery and of medicine. It may be expedient sometimes to shorten duration of stay in the interests of the total sick population, but we need not pretend that it means better nursing or medical care for the individual.

One hates to think that a hospital might be led by Dr. Cohen's hypothesis to make quick turnover of have assessed response to treatment is difficult to follow since it is not clear precisely how weight increases have been reckoned. Moreover, as is admitted in the statistical analysis, the two groups A and B are not strictly speaking controlled experiments. Is it possible to subject the results on so few cases in a disease so variable in its course and outcome to such a detailed statistical analysis?

Finally, in group C, 30 cases were given streptomycin without controls of any kind and it is claimed that they recovered surprisingly rapidly. For instance, "the speed of their response to streptomycin therapy was spectacular" in 3 cases, 2 cases "responded well to streptomycin," and more generally "It is probable that, if cases were treated with streptomycin at the onset of gastro-enteritis, starvation could be safely omitted and generous feeds given throughout the illness." This may all be true, and if it is then streptomycin will save more lives and in much smaller doses than it will ever do for tuberculous meningitis. But surely we can expect to be given more substantial evidence of the beneficial results of a new drug in the treatment of a common and dangerous disease before being encouraged in such a sweeping way to apply it indiscriminately. For that, we submit, will be the result of this paper.

Our own results, based on some fifteen months' experience of streptomycin in gastro-enteritis in the East End of London, now being collected for publication, not only confirm the findings of Dr. James and Mr. Kramer that the gut is rapidly cleared of such organisms as *Proteus vulgaris* and *P. morganii* but also indicate that these organisms rapidly reappear within a few days of withholding the drug. They suggest, moreover, that their presence, their coming and going, or their absence have little bearing on the ætiology of the disease. But we have not, unfortunately, been able to demonstrate by controlled alternately treated cases that streptomycin materially affects the course or prognosis of the disease.

This letter is written in the hope that before streptomycin is made free for general use in gastro-enteritis more convincing evidence of its efficacy will be forthcoming.

TRANSVERSE MYELITIS COMPLICATING PNEUMONIA

SIR,—Dr. Suchett-Kaye's report in your issue of Sept. 11 recalls a very similar case in this unit.

The patient, a young man of 18 in the Royal Air Force, was admitted to hospital on Nov. 7, 1947, complaining of pain in the right side of the chest. On admission his temperature was 103°F; there was a patchy erythematous rash over the face and chest, and some exudate over one tonsil. Administration of 'Sulphamezathine' was begun, and the next day he developed a cough with sputum, and increased pain in the chest aggravated by deep breathing. At this time signs of a right pleural effusion appeared, and turbid yellow fluid containing large numbers of lymphocytes was aspirated. X-ray examination of the chest revealed patchy consolidation of the right lower and middle lobes.

On the 6th day of his illness he complained of pins and needles in his legs, and by the 8th day he had a complete flaccid paraplegia with loss of all sensations below the level of the 10th dorsal segment. Lumbar puncture carried out at that time revealed a block in the spinal pathways, as evidenced by yellow fluid with a protein content of 500 mg. per 100 ml. and no response in the manometric reading following jugular compression.

He was transferred to this unit and lumbar puncture 2 days later revealed free pathways and a clear fluid. On admission he was put on heavy doses of penicillin. His right pleural cavity was aspirated on two further occasions. On the first of these a little thick pus was obtained from which a pure culture of *Staphylococcus aureus* was grown. On the second occasion there was a little turbid fluid only, which was sterile on culture.

The patient's chest condition resolved, but the paraplegia remained complete and he developed large septic pressure-sores and a urinary infection which brought about his death on April 10 this year. Autopsy reveal typical transverse myelitis of the cord with organi adhesions in the right chest over the lower lobe.

PROPRIETARY MEDICINES UNDER THE NATIONAL HEALTH SERVICE ACT

SIR,—My article of Sept. 18 (p. 465) was essential concerned with the professional use, under the A of "ethical" proprietary preparations, but as I Forster's letter of Oct. 9 introduces some wider questio I will try to answer these under general headings.

Definition.—Two types of proprietary medicines a generally recognised: (1) "ethical" preparations, s mainly on doctor's prescriptions, orders, and recor mendations, and not advertised to the lay public; a (2) preparations suitable for use without medic supervision, which can be described as "domestic proprietaries. (These two types are identified by t Chemists Federation as "class A" and "class B products.)

Uses, Including N.H.I. Prescribing.—Dr. Forster correct in saying that the more dramatic advances ethical proprietaries) were accepted under N.H.I., b his examples did not indicate the general attitude of t Ministry to these preparations. My article contain data (apparently ignored by Dr. Forster) which provid reasonable proof that the methods used to check excessi prescribing resulted in a loss of professional freed and responsibility.

Domestic proprietaries often provide a useful mea of treating minor ailments, and to bring every min disorder under medical control would seriously embarr both the medical profession and the Minister.

Methods of Control.—The Medicine and Pharma Act, 1941, the Food and Drugs Acts, and the Labelli of Foods Order, 1946 (and amending Orders), requ the disclosure of the composition of proprietaries, b there are no criteria for the official or non-official rec nition of ethical proprietary medicines such as t approved list of the American Council on Pharma and Chemistry. My suggestion was an advisory body the Minister to provide expert interpretation, whe required, of the criterion "significant therapeut advantage" (over existing *B.P.* preparations). Dr. Forst and I at least agree on the principle of a separate bod

Domestic proprietaries are controlled (1) in respe of composition, as detailed above; (2) by statuto restrictions prohibiting the non-medical treatment certain diseases specified in the Venereal Diseases A 1917, the Cancer Act, 1939, and the Pharmacy a Medicines Act, 1941; (3) in part by the standar which have been set up by such bodies as the Chemis Federation, advertising associations, and others.

The Chemists Federation has been mainly concerne with domestic proprietaries, but I must correct D Forster's assumption that the federation's purpose merely to promote the sale of proprietary preparation There are two kinds of monopoly—that which is justifie by serving the public interest and that which is no The monopoly which the federation attempts to establis for pharmacists in respect of the distribution of propri tary medicines finds its justification in the specialise knowledge of the pharmacist and the standards lai down by the C.F. Standards Committee[1]—probabl the most significant contribution yet made towards th elimination of abuses attending the sale of this class o proprietary preparation. I must also question D Forster's statement that the federation cannot complete serve two masters—the medical profession and th trade. Doctors are not directly interested in th domestic proprietary, but I am sure Dr. Forster wil agree that if both doctors and the pharmaceutica industry are serving the public welfare there will be no fundamental diversity of interests.

Pharmacy.—Dr. Forster has not, I think, taken into account the many highly specialised techniques and

---

[1] *Work of the Standards Committee.* Obtainable from the secretar Chemists Federation, 4/5, Queen Square, London, W.C.1.

) Mr. B, who had had a severe but symptomless methyl- acil neutropenia, showed an exactly similar pig- ion.

In 8 of the cases (3 non-thyrotoxic, 1 thyrotoxic ted with methyl thiouracil who had shown no toxic toms, and 4 thyrotoxic treated with methyl or l thiouracil who had shown toxic reactions) tests performed as described above but, in addition, were ted with sterile distilled water instead of methyl or l thiouracil for all injections. They were read at ame intervals as before and were all negative.

The fact that, in the cases investigated, skin tests were of no value is not surprising. In general, reactions are not constant or reliable in alimentary gy.[1] With the exception of true eczematous and, onally, true urticarial eruptions, it is generally ssible to predict by skin tests whether a person or will not show hypersensitivity to a given drug. do responses to skin tests indicate the type of clinical tion which may develop.[2]

the 8 above-mentioned cases total and differential ocyte counts were made before each of the four and at the time of each reading thereafter. One er test was performed on these patients—leucocyte ts were made at the same intervals after an trary fixed time, no injection having been given.

The number of cases in this series is far too small for eralisation. but test no. 1 showed that the total ocyte and absolute granulocyte counts fell more ipitously in the thyrotoxic patients who had iously shown toxic reactions (leucopenia and topenia) than in either the controls or the single otoxic patient on methyl thiouracil who had not iously shown toxic manifestations.

ther work is being done to confirm or refute our nal impressions.

e are indebted to Prof. E. J. Wayne and Dr. H. P. for access to their cases; and to Mr. H. J. Benzies his staff, and Dr. D. Hobson, for their help and technical tance.

COMPULSORY ADMISSION

—This morning I was compelled to go to the e of one of the casualty officers of my hospital, had been ordered to admit a chronic patient to a existent bed by an individual, apparently a doctor, d to be speaking on behalf of the Emergency Service. If this is a foretaste of official policy, its implications should be clearly understood. years ago the world was shocked by revelations the workings of an institution run on a comparable ciple. Though I am not concerned to defend the al who was in charge of that institution, there was ce in his contention that, as he had no control admissions and his protests to central bureaucracy e ignored, he was not responsible for the overcrowding neglect within his walls. His name was Kramer his institution was at Belsen. Let us not build the e for the chronic sick of England.

X.Y.

**Since July 5, the Emergency Bed Service of the 's Fund has continued to assist doctors who ask its help with the admission of urgent cases to hospitals London. The E.B.S. has no power to compel any ital to admit a patient. On the other hand, a doctor been appointed to represent the Metropolitan onal hospital boards at the E.B.S., so that when no cant bed can be found for an urgent case he may l on the appropriate hospital to make special arrange- ts for the patient's admission. It seems to us that the boards must retain the right to do this, though in ent circumstances the right should be very sparingly ised. We should be interested to hear more about is "chronic patient."—ED.L.

REGIONAL SPECIALIST COMMITTEES

SIR,—It is only six months to the end of next March, and many regions have not yet formed a representative regional specialist committee which can be certain that its delegates to the central committee really speak for the region as a whole.

In the Liverpool region we have two associations, the Hospital Staffs Association and the Regional Hospitals Medical Association, that between them cover the majority of the specialists working in the region. These two bodies have sponsored a suggestion that the Liverpool Regional Specialists Committee be reconstituted with representatives nominated as follows:

2 by the Liverpool University faculty of medicine.
8 by the Hospital Staffs Association for the teaching hospitals.
8 by the Liverpool Regional Hospitals Medical Association for the regional board hospitals.
2 by the north-western branch of the Medical Superintendents Society.
2 by the registrars, 1 to be from the teaching hospital group and 1 from the regional hospital group.
1 from the Isle of Man.

This will give a completely representative committee, and we believe that all sections will feel satisfied. We hope that any above the rank of house officer who are not already members of the Regional Hospitals Medical Association, if employed in a regional board hospital, will join us.

We are most anxious that the old difference between voluntary and municipal hospitals should not reappear in a different guise in those now set up, and we welcome the coöperation that we have received from the Hospital Staffs Association.

V. COTTON CORNWALL
Hon. Secretary, Liverpool Regional Hospitals Medical Association.

The Poplars, Lower Lane, Liverpool, 9.

THE YOUNG CONSULTANT

SIR,—It is interesting and an occasion for sympathy to read in your leading article of Oct. 16 of the meagre amount paid to general practitioners in the first quarter of the National Health Service. But the plight of the junior consultant is considerably worse than that of the general practitioner. Having spent double the time learning his job, and a not inconsiderable sum on instruments, consulting-room, and a dwelling-place, the young consultant finds that private practice has practically vanished. Conversely, hospital work has increased and a considerable amount of time and petrol has been consumed since July 5 in journeys to cottage hospitals and on domiciliary visits, to say nothing of telephone calls, stationery, and the like. The only acknowledgment of claims for payment so far received is a reference to certain domiciliary visits which are apparently not allowed for payment!

Incidentally, a promised interim payment of the staff of my hospital is still owed from July, 1947. It would be interesting to see what would be the result if sections of the so-called working class were kept waiting for fifteen months for their wages.

JUNIOR PROVINCIAL CONSULTANT.

MEDICAL RECORDS

SIR,—As a medical student, and later as a junior resident, one had the impression that potential ability was largely assessed by the accuracy and completeness of one's case-notes. Slovenly notes implied a slovenly student or house-physician, and such records used to be torn to shreds verbally and actually before an awe-struck assembly of clerks or dressers. This attitude of the chief was surely correct. Complete records can only proceed from a complete anamnesis and examination—the twin foundations of medical craftsmanship.

It would perhaps be too harsh a generalisation to translate this thesis into broader terms and state that the work of a hospital may be appraised by its clinical records, yet it is quite certain that no hospital can fulfil its purposes to best effect when encumbered by archaic methods of record-keeping. The truth of this is apparent to anyone who has experienced the contrast of work in hospitals well served and badly served in this respect.

patients its criterion of efficiency. Perhaps such a hospital would experience a rise in the number of relapsed patients who had to be readmitted; unless, indeed, they took their troubles to other institutions where results were measured in terms of health and comfort and not in numbers.

If we had to live in a house which a jerry-builder had run up on inadequate foundations in a few weeks, we should not esteem him the better workman merely because he turned out houses faster than one who built well and truly. The implications of this are infinitely more important in the building up of health and happiness.

ABORTION, STERILISATION, AND THE LAW

SIR,—The following case seems to me to be of sufficient general interest to merit discussion in your journal, and to show the necessity for a change in the present laws concerning abortion and sterilisation.

Miss X.Y., aged 31, was brought to me by her mother, with a request that I should terminate the pregnancy and sterilise the patient. She had been referred to me by two specialists in psychiatry, to one of whom she had been referred originally by her own family doctor.

The family doctor certified as follows: "I have known Miss X.Y. for ten years. She is mentally deficient and unstable and is now pregnant by an unknown man. I consider that the pregnancy should not be allowed to continue, and, as the same thing may occur again owing to her disposition, that she should be sterilised." This letter was accompanied by a letter from the rector of her village, who said: "I have known Miss X.Y. for the past ten years and have had close contact with her family for the same length of time. She is, in my opinion, unbalanced mentally, and completely unfit mentally to be responsible for the care and upbringing of a child."

Psychiatrist no. 1 certified: "I consider this patient quite unfit to proceed with her pregnancy on account of her psychiatric condition. She is mentally and emotionally unfitted for motherhood on account of her limited intelligence and emotional development. This is, in my opinion, a clear case for the termination of pregnancy and sterilisation." The second psychiatrist wrote: "The patient is very limited in intelligence and is emotionally unstable. She would be unable to look after a baby and is likely to harm it during a temper outburst. I recommend termination of pregnancy and sterilisation."

After interviewing the girl myself, I had no hesitation in agreeing that it was clearly desirable, in the girl's own interest and in the interests of the community, that the pregnancy should be interrupted, and that she should be rendered incapable of becoming pregnant in the future. But, remembering the famous case of the American millionaire's daughter who, some ten or twelve years ago, took action against her mother, who had had her sterilised, and against the doctor who had performed the operation, I wanted to make quite sure that I was not rendering myself liable either to a criminal charge, or to a civil action.

I therefore sought the advice of the Medical Defence Union, the secretary of which pointed out that none of the other three doctors or myself had certified that the continuation of the pregnancy would endanger the life, or the mental or physical health, of the mother herself, and that therefore there was no legal ground for terminating the pregnancy. He also pointed out that it was not clear whether the patient was, or was not, really capable of giving valid consent, either to termination or to sterilisation.

After exhaustive discussion, we decided, very reluctantly, that we could not safely perform either operation.

The Act forbidding abortion is far from clear. It forbids "wrongful" termination of pregnancy, without defining the meaning of the word wrongful. The interpretation generally accepted is that it is wrongful unless the continuation of the pregnancy seriously endangers the life or health of the mother. And none of us has the courage to terminate a pregnancy in a case like the present one, and so run the risk of imprisonment and loss of the right to earn our livelihood by the practice of our profession. Nevertheless, I cannot believe that any court wou find a surgeon guilty if he were to terminate the pregnan in such a case, supported, as it is, by the opinions of t patient's own usual medical attendant, her spiritu adviser, and two psychiatrists of standing.

With regard to sterilisation, the law is equally vag Some medicolegal authorities are of opinion that sterilis tion of a man or woman, sane and adult, with t patient's consent, could be regarded as *mayhem*, b according to the *Encyclopædia Britannica*, mayhe signifies an assault "whereby the injured person deprived of a member proper for his defence in figl e.g., an arm, a leg, a fore tooth, etc. The loss of an e jaw tooth, etc., was not mayhem." I do not see h sterilisation, carried out by cutting and tying the sper ducts in the male, or the fallopian tubes in the fema could possibly be interpreted as mayhem, and I belie that the voluntary sterilisation of a sane adult is n *forbidden by English law.*

But an insane or mentally defective person is render incapable, by the very fact of insanity or mental de ciency, of giving valid consent; so, in the very ca where sterilisation is most desirable, it is not permitt

Is it not time that the profession should move for t alteration of the laws relating to both abortion a sterilisation?

NORMAN HAIRE
President, Sex Education Societ

London, W.1.

TESTS FOR THIOURACIL SENSITIVITY

SIR,—There is no known régime which will guaran freedom from toxic complications, including neutropen during thiouracil therapy. Hence a simple method differentiating susceptible and non-susceptible peo would be of great value.

It occurred to one of us (E. K. B.) that skin tests association with serial leucocyte counts might fulfil t function. After consultation with Messrs. Genato Ltd., Mr. H. J. Benzies, chief pharmacist at the Ro Infirmary, Sheffield, prepared sterile solutions of met thiouracil (1/2000) and of propyl thiouracil (1/10 in distilled water. Sterilisation was effected by steam for 30 min. The preparations were put up in rubb capped bottles and kept in the refrigerator when not use, no preservative being added. Crystals occasiona separated out in the cold, the above-mentioned conce trations being near saturation level in each case. Ho ever, the crystals redissolved when the bottle was pla in warm water for about a minute.

The subjects for the tests were divided into t following groups:

(1) Non-thyrotoxic persons, 18.

(2) Untreated thyrotoxic patients, 3.

(3) Thyrotoxic patients treated with methyl or prop thiouracil who had shown no toxic reactions, 6.

(4) Thyrotoxic patients treated with methyl or prop thiouracil who had previously developed toxic ma festations, 4.

Throughout the tests the subject rested quietly in bed in a chair, no food or drink being taken, and smoking n being allowed.

Each person was submitted to *two tests:*

(1) Into one forearm 0·1 ml. of 1/2000 methyl, or 1/10 propyl, thiouracil was injected intradermally and a simil amount of sterile distilled water was injected intradermal into the other forearm as a control. Treated patients we injected with the type of thiouracil that had been given duri treatment.

(2) As in (1), except that the injections were given su cutaneously.

Readings were made after 5, 20, 40, and 60 min., an 24 and 72 hours.

These tests gave completely negative results, with tw exceptions:

(1) Mrs. A developed a light-brown pigmentation at th site of the intradermal *methyl-thiouracil* injection, aft 72 hours. This gradually faded in the next few days. Th patient had previously had agranulocytosis accompanied b a generalised erythema, following treatment with meth thiouracil.

children from Dr. Barnardo's Homes can have tment for bone diseases. His appointments included of consulting physician to the Murray Convalescent . Old Windsor, and medical referee to the Scottish ows' Fund and other assurance societies, and he d on the Home Office committee which inquired the working of the Acts for the treatment of ates. In the Hunterian society he held office president.

of the earlier motorists, he was a founder member Brooklands, and in his youth he was an enthusiast ine sports. He married in 1896 the widow of J. H. Honeyman, of Auckland, and they had twin ters. Lady Bruce-Porter died in 1937, and on her h he retired from practice to give even more time his social work, and to health education. In 1938 de a world tour during which many of his war-time ice patients were able to welcome him to their own tries. He was appointed C.M.G. in 1917 and created E. in 1919.

THE LATE DR. WESTERN

Paul Fildes writes: Dr. George Western started career as an assistant in Prof. William Bulloch's rtment at the London Hospital at a time when 's opsonic teaching was in its early stages. He collaborated with Bulloch in some early researches when I first met him in 1906 was in charge of the culation department." This department consisted Western and only Western. When 28 years later I the London Hospital "Father" Western was still in the same small room, imperturbable, reliable. wise. The "inoculation department" gradually d out and Western took over most of the contacts patients, both therapeutic and diagnostic. He made claim to being a "research-worker" but he became extremely sound and honest exponent of clinical riology. He had a high degree of technical skill was probably the first to use venepuncture as a clinical method, at a time when that sort of tory aggression was viewed somewhat askance. these methods he certainly advanced knowledge of al fever. His nickname sufficiently describes the towards him of his younger contemporaries. He ver assertive but was always there. I was not d to hear that during the recent war his sense of withdrew him from retirement in the country to a sion in the R.A.M.C.

—On Oct. 15, Arthur Harold Shepard, M.D. Dubl.

—On Oct. 11, at Bournemouth, William Legge Symes, M.R.C.S., aged 82.

Notes and News

PROTECTIVE FEARS

As the structure of the mind becomes plainer psychologists are able to generalise and classify. It is perhaps unfortunate that in the babel of medical jargon psychologists speak with a particularly obscure tongue—one that often prejudices or defeats doctors, and is presumably even less comprehensible to the layman. In his book *Conquer Fear*,[1] Mr. John Langdon-Davies sets out plainly what is now known about anxiety, irrational fears, panic states, loss of the sense of reality, and the like, and does it so well that doctors no less than laymen may be glad to read about them. He quotes many letters from the hundreds sent to him when he was writing on this subject in the *People*, and these will be of great help and comfort to people suffering from anxiety states, for they show how common such terrifying symptoms are, and how closely the pattern can repeat itself. This in itself would have been worth doing, for such people suffer a great sense of loneliness and isolation. Since their other great dread is of insanity he has wisely included one letter from a psychotic patient, to show how different are insane beliefs from those associated with anxiety; but he is careful to explain that this condition too can be treated with good hopes of success.

Books like this have been written by psychiatrists and doctors from time to time, though perhaps none with such good understanding of what the patient feels or what kinds of things he is hungry to be told. Mr. Langdon-Davies does more, for he gives some advice—and very sound advice too—on the management of these fear states by those who are suffering them. No doctor need be offended by the way he does it. He explains how impossible it would be to provide adequate psychiatric care for the large numbers affected, and makes it clear, in a tactful way, that many general practitioners simply have not been trained to deal with cases of "fear sickness"; moreover, most of them simply have not the time to do more than exclude serious physical disease and reassure the patient with a stock phrase or two. These people must either do what they can for themselves or go on for years in a crippled state.

He explains simply that these fears have a use for the patient, in that they protect him from some more painful repressed memory. What this may be they are never likely to find out: they must be content to strengthen their position in other ways. He suggests that they should write down their plans in a notebook, setting out the nature of their fears and the occasions on which they arise. Psychosomatic symptoms, once the doctor has explained they are not organic, can be looked at objectively; and depression, fatigue, boredom, and the inability to love can be related to family history and childhood memories. Here for the first time Mr. Langdon-Davies is a little obscure: it is not quite clear what the patient is to do with all the material he uncovers; for though no doubt he will ultimately be relieved merely by remembering and facing it, he will certainly have periods of increased anxiety while he is about it. This is not brought out. One important point is made extremely well, however. Many of these patients feel they are short of love; but their need is not merely, or even chiefly, to receive love but to find somewhere to put the love they have to give. If the family or friends offer no-one who can accept this affection, then it must be placed elsewhere—in socially useful work, if need be. The guilty child who is at the bottom of our irrational fears is sustained and relieved by the knowledge that he is some good to his kind.

The book should be read by relatives as well as patients, for it will make them realise that the patient is ill in the same way as if he had pneumonia or a broken leg; and it contains a good chapter on prophylaxis.

SOCIAL AND PREVENTIVE MEDICINE IN ENGLAND

THOSE who attended Sir Arthur MacNalty's FitzPatrick lectures at the Royal College of Physicians during 1946 and 1947 now have an opportunity to refresh their memory, and those who were not present will enjoy the chance of reading his careful account[2] of *The History of State Medicine in England*. The lectures cover the time from the accession of Queen Victoria in 1837 to the foundation of the Ministry

2. Published by the Royal Institute of Public Health and Hygiene. 1948. Pp. 82. 12s. 6d.

The report of the King Edward's Hospital Fund [1] will therefore be welcomed by clinicians working in hospitals where the term "records officer" is as yet meaningless. Throughout the country the advent of the National Health Service must have tended to freeze administrative initiative, and on the subject of medical records the Ministry has offered no advice. In this, as in so many other matters worthy of prompt attention, "awful darkness and silence reign over the great Gromboolian plain." Let us hope that the report may be followed by an efficient and nation-wide directive to hospital management committees, laying down the broad principles along which record departments should be planned, but leaving the initiative of reorganisation at the periphery.

Wolverhampton. J. V. S. A. DAVIES.

DENTURES AND ANÆSTHESIA

SIR,—From the Dark Ages nurses have been taught to remove the patient's dentures before the administration of an anæsthetic. The edentulous patient is left with sunken cheeks and loose, floppy, flapping lips. The sunken cheeks prevent a close fit of mask to face. The flapping lips obstruct the airway. In laryngoscopy for intubation, the laryngoscope may cut the gum and slip from side to side. If the denture be left in place laryngoscopy is more easily accomplished, and the teeth can be protected by a piece of strapping. For the past ten years I have made a practice of leaving all *full* dentures in position, without accident of any kind.

Last, but not least, some lady patients suffer intense distress when appearing in the theatre as "toothless old hags," as one poor victim put it. There can be no risk in leaving a full set in position so long as the anæsthetist knows they are there. He is no anæsthetist if he has not looked.

Carshalton. H. PARRY-PRICE.

Obituary

JOHN WILLIAM SCOTT MACFIE

M.A. CAMB., M.B., D.SC. EDIN., D.T.M.

WE have to record the death at St. Leonards on Oct. 11 of Dr. J. W. S. Macfie, a worker of eminence and erudition in many branches of tropical medicine. Born in 1879, he was educated at Oundle, at Cambridge, and at Edinburgh, where he graduated in medicine in 1906. After working in various laboratories, including the physiology laboratory at Liverpool under Sherrington, his interests turned to tropical medicine. He took the diploma in tropical medicine at Liverpool in 1910 and then went to West Africa, where he served on the medical staff from 1910 to 1923 and was director of the Medical Research Institute at Accra from 1914 onwards. During this time he contributed much to knowledge by his work on a variety of tropical diseases, especially trypanosomiasis and malaria. In 1917 he was seconded to the Liverpool School of Tropical Medicine to undertake special research on malaria, and in 1919 he was awarded the school's Mary Kingsley medal for distinguished achievement in the field of tropical medicine.

On retiring from West Africa Macfie joined the staff of the Liverpool School of Tropical Medicine as lecturer in protozoology, and later he worked on the chemotherapy of malaria, under the ægis of the Medical Research Council, at the London School of Hygiene and Tropical Medicine. In 1935, despite failing health, he went to Ethiopia as a member of the British Red Cross unit serving in that country; a record of those experiences was subsequently published in *An Ethiopian Diary*. In 1941, on his insistent request, he was appointed to the Royal Army Medical Corps for overseas duty, and he served with distinction in nos. 3 and 8 malaria field laboratories in Egypt and in the Middle East as a malariologist until a breakdown in health in 1943 obliged him to return to this country. Here he renewed his old interest in taxonomic studies at the British Museum; and he went back for a short time to the Liverpool School of Tropical Medicine, where he was engaged in preparing an instructional film on malaria. Macfie was a world authority on the midges (Cera pogonidæ), and was largely responsible for the ident cation and classification of the collection of these ins in the British Museum. Tall and ascetic, he ha kindliness and an unassuming mien that endeared equally to his contemporaries and to his junior colleag many of whom recall with gratitude his unostentati benefactions.

CHARLES EDWARD LACEY

M.B. LEEDS, D.P.M.

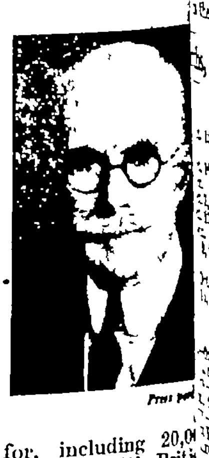
Dr. C. E. Lacey died on Oct. 3 at the age of 29 at National Hospital, Queen Square, where he was regis of the psychiatric department. A Yorkshireman, he educated at Knaresborough Grammar School and Leeds University, where, after earning many distinct and scholarships, he graduated in 1942. Six mo later he joined the Army, in which he served till 1 and as section officer of a parachute field ambul he took part in the invasion of Europe. After a ye training in general medicine in Leeds and Bradford was awarded a fellowship in psychiatry at Crich Royal, Dumfries.

W. M.-G. writes: "Strict and critical with him kind and cheerful with others, Lacey was imbued an ardent love of life. His keen and penetrating m his quick grasp of essentials, and his natural gift physician gave legitimate hope that a useful career before him as a specialist of academic standing. Certa psychiatry can ill afford to lose a young man of ability and character."

Dr. Lacey married Dr. Gaynor Jones, who is als psychiatrist.

HARRY EDWIN BRUCE BRUCE-PORTER

K.B.E., C.M.G., M.D. BRUX., M.R.C.S.



Sir Bruce Bruce-Porter, who died at his daught home in Somerset on Oct. 15 at the age of 79, will widely remembered for his forceful but kindly personal his zeal in many good causes, and his ability to public attention for them. He was born at Woolw the son of Captain J. Porter, R.A. At the London Hosp he won scholarships in anatomy, physiology, and clin medicine, and also the Duckworth Nelson scholarshi practical medicine and surgery. He qualified in 1892, two years later, after postgraduate study in Brussels Vienna, obtained his M.D. Brux. with distinction. At the Army Medical School at Netley in 1893 he obtained honourable mention in military medicine, clinical medicine, and surgery. After holding a commission as surgeon captain on the Army medical staff he returned to civilian practice, but he retained his connexions with his old service both as a Territorial and as physician to the King Edward VII Hospital for Officers. When war broke out in 1914 he held the rank of lieut.-colonel and was placed in administrative charge of the 3rd London General Hospital at Wandsworth. In this hospital, which ultimately had 2600 beds, many Dominion troops were cared for, including 20,0 Australians. In 1916 he commanded the 40th Briti General Hospital in Mesopotamia. For many years h was a military member of the council of the Territori Force Association in London.

Bruce-Porter's military background made natural th devotion he gave to the work of the St. John Ambulan Association and the Red Cross, of whose joint coun he was formerly a member. A knight of grace of th Order of St. John of Jerusalem in England, he was member of the order's general chapter. But his wor for charity was many-sided: he helped to secure reco nition for blind masseurs, he was vice-president the Shaftesbury Society and Ragged School Union, and he gave special interest to the Bruce Porter Hom

ity of Liverpool

Oct. 15 the following degrees were conferred:

—J. R. MacLeod, D. E. Paterson.

ersity of Sheffield

John Chisholm, who has held the chair of obstetrics gynæcology since 1935, has become part-time director department of obstetrics and gynæcology. He will to hold his post on the staff of the Jessop Hospital. William Hobson has been appointed to the new chair and industrial medicine.

Hobson, who is at present senior lecturer in preventive in the University of Bristol, and honorary assistant officer of health to the city of Bristol, took his B.Sc. at first-class honours in 1933. Three years later he took and became lecturer in physiology and hygiene in the of Leeds, a post which he held till 1938, when he was assistant school medical officer for Leeds. The following year, he also took his M.D. with distinction, he became assistant Hampshire, and in 1940 M.O.H. for Lymington. From 1945 Dr. Hobson served in the R.A.M.C. as a specialist and he was mentioned in despatches. His published a paper on urinary output of creatine and creatinine with physical exercise and its relationship to carbohydrate

Tom Smith has been appointed temporary lecturer and gynæcology. Dr. Jeanne Montgomery to the medical officer for the student health service, J. B. Pyper demonstrator in anatomy. Dr. J. A. Dr. D. H. Randall, and Dr. J. Maclean Smith have tutors in medicine, surgery, and medical pathology and Dr. J. K. A. Beverley and Dr. Sheila M. honorary demonstrators in bacteriology.

College of Surgeons of England

a meeting of the council held on Oct. 14, with Lord Johnson, the president, in the chair, Prof. Geoffrey was admitted as Sir William Collins professor of and comparative pathology, and the John Tomes presented to Prof. H. H. Stones, Liverpool. The in dental surgery was awarded to Dr. Harvey H. Canada, and Prof. B. Gottlieb, Austria.

J. H. Dible was appointed examiner in pathology forthcoming primary fellowship examination in Ceylon. of membership were granted to R. B. Heisch, and D. H. K. Soltau. The following diplomas ted jointly with the Royal College of Physicians:

—T. S. Adisubramaniam, M. A. C. Dowling, William Gunn, ta, E. T. Harrison, G. O. Hughes, T. H. McCormack, ller, J. B. Sherman, J. A. Smiley, J. M. Stuart, A. R.

M. & H.—C. S. Agrawal, M. H. S. E. Amroussi, Norah H. C. P. Courtenay-Mayers, K. O. Courtney, R. M. Cross, H. G. Edmunds, Walter Fabisch, J. D. Grene, J. T. G. F. Houston, M. H. Hughes, S. A. Jones, Ronald Lwin, McHugh, B. U. Mistry, Mok Hing Yiu, Radhagovind Mariano Rech, A. S. Saffar, M. A. E. Sayed, S. C. Sekar, F. K. Shah, W. D. L. Smith, M. L. Sur, Eustachy G. H. Wattley, Wu Hsueh-Tsung.

M.S.—P. C. Agarwal, A. N. Ashworth, N. L. Bailey, S. C. G. M. Barling, B. A. Bembridge, T. A. S. Boyd, R. S. E. J. B. Bunting, Thomas Chadderton, R. M. Chambers, Chan, P. M. Chaudhuri, E. S. Dismorr, N. F. Donaldson, J. H. W. Fagan, P. I. Franks, Samuel Galbraith, mley, T. B. Gupta, Ko Gyi, Andrew Harrison, J. R. P. J. L. Hunter, R. I. Jaffe, K. R. Kesavachar, T. G. rell Lerner, H. F. T. Merchant, A. Michelmore, Dorothy J. Miller, R. G. Mitchell, E. S. J. N. Montgomery, Norrene M. Nicholson, W. B. O'Driscoll, Jack Pelunsky, A. P. Radford, Elizabeth Radovitch, Short, G. A. V. Ribeiro, Frank Riley, B. S. Rose, Mutarika Shah, Gwendolen D. Smith, Peter Stevens, land, P. V. Suckling, Jean C. Taylor, K. B. Thornton, C. H. C. Upjohn, D. F. Van Zwanenberg, D. G. G. F. Walker, J. M. Watt, L. E. Wear, S. D. V. Weller, Jean C. Willison, B. S. B. Wood, L. A. Zeki.

Royal College of Obstetricians and Gynæcologists

At a meeting of the council held on Oct. 1, with Sir William Gilliatt, the president, in the chair, the honorary fellowship was conferred on Dr. Emil Novak of Baltimore. Dr. A. F. Hollinrake (Ontario) was admitted to the fellowship, and the following to the membership:

I. S. R. Bain, Henrietta E. Banting, T. L. S. Baynes, Samuel Behrman, D. C. A. Bevis, C. C. Bowley, T. St. V. W. Buss, L. W. Cox, Mary E. Egerton, T. E. Elliot, G. McL. Forsyth, H. D. Freeth, G. T. Gibson, J. H. Gibson, Andrew Graham, A. H. Grenz, Constance A. Grey, H. B. Hattam, C. C. Henneberg, Ebbie Hesselberg, D. W. Hirson, J. C. Holman, K. R. Hudson, A. G. Jones, J. B. Joyce, W. T. Kenny, G. G. Kerster, R. A. H. Kinch, Samuel Lask, T. L. T. Lewis, E. L. F. McConnachie, William Macfarlane, J. M. McKiddie, S. H. Madden, Helen M. Mayer, G. W. H. Millington, F. L. E. Musgrove, J. R. Norris, J. J. F. O'Sullivan, J. H. Patterson, A. C. Pearson, W. H. Peck, S. D. Perchard, David Pryor-Jones, E. H. Rees, S. McR. Reid, H. A. Ripman, D. N. S. Robertson, B. W. Sanderson, G. A. Silley, A. A. Smith, Tom Smith, G. J. Sophian, Christine M. Stacey, P. C. Steptoe, C. S. N. Swan, R. A. Thatcher, G. S. Thomas, R. G. Whitelaw, R. M. Williams, M. S. Williamson, H. G. Wolskel, P. S. Wright, R. B. Wright.

A postgraduate course in the practice of obstetrics and gynæcology will be held at the college from Nov. 15 to 19. Further particulars will be found in our advertisement columns.

Royal Medico-Psychological Association

On Friday, Nov. 12, at 2.15 P.M., at 26, Portland Place, London, W.1, Mr. Claud Mullins, late Metropolitan police-court magistrate, will deliver the Maudsley lecture. He is to speak on Psychiatry in the Criminal Courts.

Pharmaceutical Society of Great Britain

Dr. C. H. Hampshire, secretary of the British Pharmacopœia Commission, will speak on the British Pharmacopœia, 1948, at a meeting to be held at 17, Bloomsbury Square, London, W.C.1, on Thursday, Oct. 28, at 7.30 P.M. The lecture will deal generally with the pharmacopœia, as an introduction to a course of seven weekly lectures.

Public Health and Municipal Engineering Congress and Exhibition

Mr. Aneurin Bevan, the Minister of Health, will open this congress and exhibition at noon on Monday, Nov. 15, at Olympia. The Ministries of Works, Food, and Agriculture and Fisheries and the Department of Scientific and Industrial Research, are to be among the 168 exhibitors. The congress and exhibition will continue until Nov. 20.

More Nurses and Midwives

Full-time nursing and midwifery staffs in hospitals in England and Wales have risen by 2000 in twelve months. In June, 1948, the total, including those trained and in training, was 117,000, compared with 115,000 a year earlier. Part-time nursing and midwifery hospital staffs over the same period rose by nearly 7000—from 10,700 to 17,380. These increases have made it possible to reopen beds closed through lack of staff, and of the 63,000 previously out of action for this reason nearly 6000 were again available for patients by June this year. The Ministry of Health says: "The point has now been reached when every addition to the hospital nursing and midwifery staffs means either the opening of more beds or the improvement of working hours and conditions, or sometimes both."

R.S.M. Microfilm Unit

Thanks to a generous grant from the Rockefeller Foundation and the practical help of the Ministry of Health, Board of Trade, and Foreign Office, a finely equipped microfilm unit has been completed at Dering Yard, off Bond Street, for the Royal Society of Medicine. At the inauguration on Monday evening Sir Henry Dale, F.R.S., the society's president, explained that its work of duplicating medical papers and other documents began in the late war, as a scheme for keeping base hospitals informed. Microfilm projectors were provided by the society at hospitals ranging from the Rhine to Delhi, and the Royal Air Force transported the films from London. A Rockefeller endowment in 1945 made it possible to apply the microfilm service to the big task of filling gaps in the journal files of medical libraries in Europe and elsewhere. Already 3500 unobtainable back-volumes of journals have been duplicated and supplied; and it is hoped that the present unit, with its production capacity of 25,000 pages on microfilm a day, will be able to meet the large number of orders still outstanding.

of Health in 1919; but since preventive medicine, though intimately linked with it, has a much longer history than State medicine, Sir Arthur has included, as an introduction to the volume, his presidential address to the Royal Society of Medicine's section of the history of medicine, in which he reviewed the growth of the preventive idea from the days of ancient Egypt and Greece up to the time of the Industrial Revolution and the great social reformers.

UNION OF ST. LUKE

WE have received the first periodical letter issued by the Union of St. Luke, which was founded this year and has the Bishop of Ely as its president. The union is a professional association of medical practitioners who are communicant members of the Church of England. "It aims to assist such practitioners by means of its fellowship to strengthen their Christian life and witness." The hon. secretary is Dr. R. H. Hardy, 5c, Parkhill Road, London, N.W.3.

CLEANER FOOD

AT their annual conference at Hastings on Oct. 14, the National Council of Women adopted a comprehensive resolution urging the Government to put an end to the loss of food by contamination, by making it compulsory for all local authorities to pass and enforce adequate by-laws for the protection and clean handling of all foodstuffs. The conference, says the *Manchester Guardian* of Oct. 15, also called on the Minister of Health to repeal the exemption clause in section 14 of the Food and Drugs Act, 1938, so that restaurants, inns, &c., would have to be registered in the same way as premises which sell cooked foods over the counter, and demanded a high standard of cleanliness and comfort in trains and railway refreshment rooms and improvement in the standard of food supplied in refreshment rooms.

NECROPSY ON A TRANSFIXIONIST

DETAILS have now been published [1] of the necropsy on Mirin Dajo, who, after surviving transfixion with swords and rods many hundred times, died after swallowing a dagger.[2] Œsophagoscopy revealed that the point of the dagger, which was nearly 14 in. long, had perforated the œsophagus, its blunt head being in the stomach. The dagger was removed by gastrotomy. The wound in the œsophagus healed, and on the seventh day, when the stitches were removed, Dajo seemed well; but about a week later he was found dead. Necropsy showed that local mediastinitis had arisen at the site of perforation and had led to erosion of, and hæmorrhage from, the aorta, which had presumably been scratched by the point of the dagger. Relics of Mirin Dajo's previous multiple transfixions were numerous pleural adhesions (but very few peritoneal adhesions), scars in the liver, and a single scar in the apex of the heart.

AMBULANCE AND FIRE SERVICES

THE Institute of Certified Ambulance Personnel, of which Dr. H. B. W. Morgan, M.P., is president, and Dr. W. W. Fox chairman, was set up to raise the standards of knowledge and service of ambulance personnel and "to minimise the needless pain and suffering which many patients have to undergo when they are transported in ambulances by men whose knowledge, training, and experience is below the standard necessary for their full efficiency." The institute rightly takes its responsibilities seriously, and a recent memorandum by Dr. Fox on the future administration of the ambulance service under the National Health Service Act discusses how far ambulance personnel can usefully be helped in their work by their colleagues, the members of the fire service. Coördination between the two services in the repair and maintenance of vehicles and intertelephonic communications would be welcome as an economy in man-power; but coöperation in the care of the patient is regarded with more reserve. Firemen are trained to deal with the restriction of fire on property and "their whole psychological outlook is one which is associated with destruction; hacking down of timber and using powerful jets." Handling the injured requires a high standard of gentleness and one cannot, Dr. Fox suggests, expect to develop these two qualities in the same person. His memorandum asks readers to consider "what qualifications you would like the individuals to have who would be responsible for your personal transportation."

HOMES FOR THE AGED IN LONDON

LONDON County Council has arranged to purchase houses for use as small homes for the aged. This is in pursu of the council's policy, under the National Assistance of establishing such homes in various parts of London wher they are needed. Each home is to accommodate not than 80 old people, and the aim is that they shall take siderably fewer. Development of the scheme is likely t slow, for no new building is to be undertaken, and the am of money to be devoted to conversion is restricted.

MALARIA CONTROL IN SARDINIA

THE Italian public-health authorities claim great str in the prevention of malaria in Sardinia (which is abou large as Wales), with the help of the Rockefeller Foundat by an attack on mosquitoes and their larvæ with D.D.T. 'Oktaklor.' [1] In 1946 there were 17,000 cases of malari the medical district of Cagliari, the southern capital of island. In 1947 the figure dropped to 6000, of which 1000 were primary infections, and in the first half of to 456 cases, of which only 21 were primary infections.

INTERNATIONAL SCIENTIFIC FILM CONGRESS

AS mentioned in our last issue this congress, held in Lon between Oct. 8 and 12, was attended by delegates 25 countries, who agreed to establish an International S tific Film Association. Among the matters to be consid by subcommittees are: (1) the establishment of an i national data card for compiling a master index of scien films available throughout the world and the formulatio methods of appraisal of these films; (2) the joint produc by a number of countries of films of common interest; (3) exchange and distribution of scientific films and the cust regulations affecting such exchange; (4) the setting up scientific film reference library; and (5) the exchang information between nations by means of a regular jou

SCHOOL OF PHARMACY

THE transfer from the Pharmaceutical Society of resp bility for the government of what has lately been kn as the College of the Pharmaceutical Society, was annou by Prof. H. Berry, the dean, at the opening of the new se on Oct. 6. The college, which is now reconstituted o independent basis within the University of London, be known as the School of Pharmacy. In addition to dean, the governing body has the following members:

Nominated by the university.—Mr. O. L. Brady, D.SC., Sir Arch Gray, F.R.C.P., Mr. J. B. Hunter, F.R.C.S., and Mr. G. B. D.SC., F.R.S.

Nominated by the academic board of the college.—Prof. G. Buttle, M.R.C.S., Miss Katharine Coward, D.SC., Mr. J. W. Fair PH.D., and Prof. W. H. Linnell.

Nominated by the Pharmaceutical Society.—Mr. W. S. Ho Mrs. J. K. Irvine, Mr. H. N. Linstead, and Mr. C. W. Maplethe

Coöpted members.—Sir Henry Dale, O.M., F.R.C.P., Mr. W. J Quarrell, and Sir Harry Jephcott (chairman).

Mr. S. R. Curtis has been appointed secretary to the sch

University of London

At a recent examination for the diploma in medical radio the following were successful:

J. C. Bulstrode, J. G. L. Cole, J. C. A. L. Colenbrander, J. Latto, Daniel O'Connell, J. H. O'Connell, Basil Stoll, R. D. St. Tucker, A. H. N. Wellkala.

Mr. G. Ewart Martin will deliver the Semon lecture 1, Wimpole Street, W.1, on Thursday, Nov. 4, at 4 He has chosen as his subject Broncho-œsophagology Great Britain.

On Tuesday, Nov. 16, at 5 P.M., Dr. Charles Swan speak on Rubella in Pregnancy as an Ætiological Factor Congenital Malformations and Stillbirth; and on Frid Nov. 26, at 5.30 P.M., Prof. Dugald Baird on Social Fact in Obstetrics. Both lectures will be given at the Westmin Medical School, Horseferry Road, S.W.1.

Royal College of Physicians of London

On St. Luke's Day, Oct. 18, Dr. F. M. R. Walshe, F delivered the Harveian oration which is summarised p. 660. After the oration the Weber-Parkes medal and pr were presented to Dr. S. Roodhouse Gloyne. This pr is awarded triennially for the best work done on the ætiolo prevention, pathology, or treatment of tuberculosis.

TREATMENT OF THYROTOXICOSIS

REVIEW OF 350 CASES

SIR CARRICK ROBERTSON
M.B. Lond., F.R.C.S., F.R.A.C.S.
F OF STAFF, MATER MISERICORDIÆ HOSPITAL, AUCKLAND,
NEW ZEALAND; CONSULTING SURGEON, AUCKLAND HOSPITAL

This paper is based on clinical observations on 350 of thyrotoxicosis treated between January, 1945. September, 1947.

During this period all patients with thyrotoxicosis re had suggested to them trial of the thio compounds, never it was thought likely that they would benefit but here lies the difficulty. At first there were no eria to guide one, and even now there are too few; , as experience grows, it is becoming a little easier dvise patients which course to pursue.

Of the 350 only 111 were treated with thiouracil; so this series the scales are rather heavily weighted on surgical side, the reasons being that many of the ients were sent by practitioners as cases for operation, the patients had already decided that they preferred gery to protracted medical treatment.

These 111 patients treated with thiouracil have been vided into three age-groups, since the younger patients em more often to achieve a permanent cure on thiouracil an do the older ones:

e-group (years)	No. of patients	No. improved
Under 21	16	10 (62%)
21–45	73	29 (40%)
Over 45	22	11 (50%)
	111	50 (45%)

the last group all the goitres were nodular and t of the patients had been thyrotoxic for years; y were bad surgical risks. The 11 patients who roved were very pleased with the result, in spite of ct that they still had palpable and visible goitres e were not entirely cured of fibrillation. Apart these 11 were others who had, in addition, a very blood-pressure. All of these hypertensive thyro were treated with thiouracil, and in none was blood-pressure lessened, nor did the treatment raise enthusiasm on the part of the patient. Those who equently underwent operation professed themselves h better, though there was still no great difference the hypertension—perhaps a somewhat similar experi e to that found in cases of hypertension treated by mpathectomy. The only thing this age-grouping shows slightly better response to thiouracil in the youngest up.

NTRA-INDICATIONS TO TREATMENT WITH THIOURACIL

On reviewing the failures of this treatment we now reasonably certain that the following are ntra-indications to the use of thiouracil:

(1) *Signs of Pressure on the Airway.*—In nearly every the goitre enlarges in the first few weeks of treatment th thiouracil. I have seen it stated that enlargement ly takes place when too large a dose of thiouracil been given, but I cannot altogether agree with s statement. I believe that, whatever dose is given, largement usually follows. A microscopical section a thyroid gland in a patient taking thio compounds ows hyperplasia of the cells lining the vesicles as great , and similar to, that seen in Graves's disease or primary yrotoxicosis. Therefore the first contra-indication to the exhibition of thiouracil is any pressure on the airway. This obstruction may be obvious to the merest tyro, in the cases with lateral displacement of the trachea or those with whistling inspiration, but even in a small oitre an insignificant nodule (see below) or a high pper pole (see below), unseen and impalpable because of its retrotracheal position, can cause considerable discomfort, which will be made worse when the goitre is increased by the administration of thiouracil. This is a cogent reason for preferring surgery, with its almost negligible risk, for all nodular goitres.

(2) *Toxic Nodular Goitre.*—All elderly patients with a toxic nodular thyroid gland have grown up with their goitre and little realise how ill they have become, because the change from simple to toxic goitre is slow and insidious. They are bad surgical risks and doubtless should be given the opportunity of thio treatment, but it must be granted that operation more quickly relieves shortness of breath by rapid improvement in the heart action and by removal of pressure on the airway. However ill these patients look when first seen, it is surprising how often they become safe risks after a week or ten days in hospital under suitable medical treatment; if they do not improve in that time, they are not safe risks. It is in these cases, and these cases only, that we practise a two-stage operation; and, if one's mind is made up before the surgical attack that a two-stage operation is safer, it is well to stick to that opinion, however easy and simple the first half of the operation may be. My own opinion is that toxic nodular goitre should be treated by surgery with very few exceptions.

There is little difference between the toxic symptoms of the hyperplastic and of the toxic nodular thyroid glands. Microscopically the nodular goitre is seen to have hyperplastic tissue in the parts of the nodules or surrounding tissue similar in all respects to the hyperplasia seen in Graves's disease. So, if thiouracil is good for one, why not for the other? The answer is that, though the symptoms may be relieved, the patient is not satisfied; and I offer the following explanation.

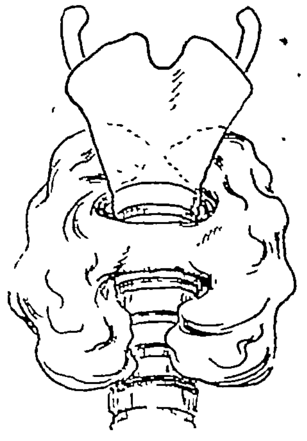

Diagram of upper poles of a toxic goitre winding round the back of the larynx. The right upper pole contains a small nodule or adenoma.

It is not uncommon to see, at operation on a large nodular goitre, an indentation or softening of the trachea as the result of pressure. But it does not appear to be commonly recognised that, even in small nodular goitres, a small nodule in the deeper part of the thyroid gland may have insinuated itself between the vertebræ and the œsophagotracheal tract. This cannot be seen or palpated until the gland has been exposed at operation. Whenever a nodule is found behind the trachea, it is shiny, glistening, and greyish, like a waterworn stone. Probably this appearance is due to thickening of the capsule by the up and down movement of the trachea during swallowing. In these cases there is no indentation of the trachea, but the nodule or the enlarged upper pole must cause discomfort, such as a tight feeling in the neck, often more obvious during swallowing.

(3) *Retrolaryngeal Upper Pole of Thyroid Gland* (see figure).—Several patients with hyperthyroidism and little apparent goitre, but only the smooth gland of Graves's disease, were treated with thiouracil for 2–4 months but refused to carry on and demanded surgery. They found difficulty in explaining why. According to the basal metabolic rate (B.M.R.) they should have felt better, but they were obviously unhappy and had an ill-defined discomfort in the neck—a sort of goitre-consciousness. At first it was thought that they were

No. 2 (Br.) General Hospital

The second reunion dinner for ex-members of this Army unit is being held on Saturday, Nov. 13. The organiser is Dr. J. H. Easton, 42, Pembury Road, Tonbridge, Kent.

Royal Institute of Public Health and Hygiene

Sir Lionel Whitby will deliver the Harben lectures at the institute, 28, Portland Place, London, W.1, on Tuesday, Wednesday, and Thursday, Dec. 7, 8, and 9, at 3 P.M. He is to speak on Hæmopoiesis.

Extra Food for the Tuberculous

The Ministry of Food has explained that patients with active tuberculosis are allowed each week, besides their ordinary rations, 1 oz. of bacon, ½ oz. of cooking fat, and 3 oz. of butter or margarine. They are entitled to three eggs and 14 pints of milk.

W.H.O. Regional Office

A regional office for south-east Asia is shortly to be set up by the World Health Organisation; this will serve India, Ceylon, Thailand, Burma, and Afghanistan. It is proposed that other regional offices should be established for Africa, the Eastern Mediterannean, the Western Pacific, and the American continent.

Rehabilitation: a Course for Foreign Visitors

The British Council is holding a course on Rehabilitation and Resettlement of the Disabled, which began in London on Oct. 18 and which will be continued at Mansfield and Birmingham. Some 20 visitors from Europe and China are attending the course, which was organised in response to requests from specialists in Europe who wished to see what Britain is doing in this field. The medical part of the course has been arranged by Dr. Harold Balme, medical officer in charge of rehabilitation, Ministry of Health.

Polarography in Biochemistry

A discussion on this subject will be held by the polarographic discussion panel of the Society of Public Analysts and Other Analytical Chemists at 3.45 P.M. on Friday, Oct. 29, at the Imperial College of Science and Technology, South Kensington, London, S.W.7. Mrs. A. M. Robinson, PH.D., and Mr. F. L. Warren, D.SC., will speak on Applications of Polarography in the Diagnosis and Treatment of Cancer, Mr. Tudor S. G. Jones, PH.D., on the Determination of Amino-acids by Polarographic Reduction of their Copper Complexes, and Mr. J. E. Page, PH.D., on the Polarography of Penicillin.

Liverpool Regional Hospital Board

At a meeting held on Oct. 7 the board approved an estimate of expenditure for 1949–50 of £7,160,280, of which £597,282 is to be spent on capital work at hospitals. No guidance has been received from the Ministry of Health as to the total expenditure on capital work to be allowed by the board, and it was agreed to acquaint the Ministry with the full needs of the region. The board estimated that works begun in 1949–50 would require a further expenditure of approximately £900,000 in the financial year 1950–51.

The board approved in principle the proposal to erect a first stage of a new mental-deficiency institution at Greaves Hall, Banks, near Southport, at a cost of £2,000,000.

Return to Practice

The Central Medical War Committee announces that Mr. Gilbert Parker, F.R.C.S.E., has resumed civilian practice at 25, The Crescent, Linthorpe, Middlesbrough.

Dr. A. C. Norman has been appointed to the third class (civil division) of the Order of Al Rafidain in recognition of his services as director of the X-ray institute at the Royal College of Medicine, Baghdad.

Major-General R. J. Blackham, M.D., on completion of 21 years' service as clerk of the Worshipful Company of Glaziers and Painters of Glass, has been unanimously elected an honorary member of the court of assistants of the company. The court and livery of the Glaziers Company also presented him with an antique clock and a cheque.

Appointments

CASE, R. A. M., M.B., PH.D. Birm.: fellow, Chester Beatty Insti for Cancer Research, London.

MACKENZIE, N. F., M.B. Edin., DIP. PSYCH.: superintendent, N church Home, Culcheth; adviser to the Liverpool Reg Hospital Board on mental deficiency problems and super of the board's smaller mental deficiency establishments.

RAVEN, R. W., O.B.E., F.R.C.S.: visiting surgeon, Star and Ga Home for Disabled Sailors, Soldiers, and Airmen.

Hospital for Sick Children, Great Ormond St., London:

BLACK, J. A., M.B. Camb., M.R.C.P.: asst. medical reg gastro-enteritis flying squad and hospital gastro-ente unit.

COWAN, R. J., M.D.: house-surgeon, orthopædic departm

DAVIES, PAMELA, M.B. Glasg.: asst. resident M.O., Tadw Court.

MACOUN, S. J. R., B.A., M.B. Camb., M.R.C.P.: house-physic

SAVAGE, T. R., M.A., B.M. Oxfd, M.R.C.P.: house-physician

London County Council Public Health Department:

Asst. divisional M.O.:

ATLEE, C. N., M.D. Durh., M.R.C.P., D.P.H.
BUTLER, LILY, M.R.C.S., D.P.H.
LOW, J. B., M.B. Edin., D.P.H.
POLHILL, M. C., M.R.C.S., D.P.H.
SIMPSON, R. H., M.D. Lond., F.R.C.P., D.T.M. & H., D.P.H.

Diary of the Week

OCT. 24 TO 30

Monday, 25th

SOCIETY OF APOTHECARIES, Black Friars Lane, E.C.4
4 P.M. Dr. Basil Parsons-Smith: Hypertension.
MEDICAL SOCIETY OF LONDON, 11, Chandos Street, W.1
8.30 P.M. Dr. Jack Rubie, Dr. Geoffrey Marshall: Streptom

Tuesday, 26th

INSTITUTE OF DERMATOLOGY, 5, Lisle Street, W.C.2
5 P.M. Dr. A. D. Porter: Liver Function in Certain Dis of the Skin.
INSTITUTE OF LARYNGOLOGY & OTOLOGY, 330, Gray's Inn R W.C.1
2.30 P.M. Mr. W. A. Mill: Malignant Diseases and Radiothe
EUGENICS SOCIETY
5.30 P.M. (Burlington House, Piccadilly, W.1.) Mr. Cecil Bin Legal and Social Implications of Artificial Insemina

Wednesday, 27th

SOCIETY OF APOTHECARIES
5 P.M. Prof. Henry Cohen: Therapy as a Diagnostic Me
ST. JOHN'S HOSPITAL DERMATOLOGICAL SOCIETY
4.30 P.M. (1, Wimpole Street, W.1.) Dr. J. M. H. MacL Milestones on a Dermatological Journey. (Prosser W oration.)
MEDICO-LEGAL SOCIETY
8.15 P.M. (26, Portland Place, W.1.) Judge Earengey: Justice.
ROYAL INSTITUTE OF PUBLIC HEALTH & HYGIENE, 28, Port Place, W.1
3.30 P.M. Dr. C. Fraser Brockington: Problem Families.
UNIVERSITY OF GLASGOW
8 P.M. (Department of Ophthalmology.) *Prof. A. Loewenst* Histopathology of the Drainage Angle.

Thursday, 28th

SOCIETY OF APOTHECARIES
5 P.M. Sir Stanford Cade: Management of Inoperable Malig Disease.
INSTITUTE OF NEUROLOGY, National Hospital, Queen Square, W
5 P.M. Prof. E. G. T. Liddell: *Integration—Then and Now*
LLOYD ROBERTS LECTURE
4.30 P.M. (St. Mary's Hospitals, Manchester.) Mr. R. M. Titm Parenthood and Social Change.
CHADWICK LECTURE
4 P.M. (University College, Nottingham.) Sir Arthur MacNa Advances in Preventive Medicine during the Wa 1939–45.
HONEYMAN GILLESPIE LECTURE
5 P.M. (Edinburgh Royal Infirmary.) Dr. R. G. Gordon: Psy genic Pain.

Friday, 29th

MEDICAL SOCIETY FOR THE STUDY OF VENEREAL DISEASES
8 P.M. (11, Chandos Street, W.1.) Mr. Reynold Hord: V.D. Factor in Infertility and Sterility and its Treatm

Saturday, 30th

BIOCHEMICAL SOCIETY
11 A.M. (London School of Hygiene, Keppel Street, W.C Symposium on Partition Chromatography and its App tion to Biochemical Problems. (This notice was incorre included in last week's Diary.)

CORRIGENDUM: *Conference on Infertility.*—The subst used by Dr. Ernst Friedman in hysterosalpingography (Lan Oct. 2, p. 543) is 'Viskiosol 6,' made by Messrs. May & Bak Ltd.

MENINGOCOCCOSIS

A PROTEAN DISEASE*

H. STANLEY BANKS
M.D. Glasg., F.R.C.P., D.P.H.
CIAN-SUPERINTENDENT, PARK HOSPITAL, HITHER GREEN

(*Concluded from p. 640*)

Complications and Sequelæ

Not only the varieties of meningococcosis but also what usually termed its complications bear witness to the tean nature of this infection. Complications have considerably reduced both in number and scope chemotherapy. For example, pericarditis and neuro-ulitis, formerly not uncommon, were not observed y series of 706 cases. The most significant reduction, ever, is in hydrocephalus and the chronic form of disease. The three most common complications now labyrinthitis, arthritis, and cranial-nerve palsies, d, of these, only labyrinthitis leaves sequelæ. The manent deafness resulting from labyrinthitis is by the most important residuum among those who over from the disease.

LABYRINTHITIS

Labyrinthitis is due to infection of the perilymph rough its direct connexion with the subarachnoid ce. As a rule both vestibule and cochlea are affected. vestibular lesion produces a defect of balance which mains until it is compensated by re-education of pro-oceptive and visual mechanisms, usually after a few nths. The cochlear lesion affects the organ of Corti ally or partially, producing perception-deafness (nerve-afness). Unfortunately the damage is done at an rly stage of the disease, commonly on the second or d day; so the chances are against recovery from ess, even with prompt sulphonamide therapy. In perience the deafness is transient for a few days s in about 1 in 6 of all cases in which deafness is in the acute stage. In a minority of the remainder vement takes place for a few weeks, or rarely for months, after the onset. Permanent deafness in or both ears, total or partial, is the sad lot of all the transient cases, and most of them are in children young adults. In my series the risk of contracting ness appeared to be about 5–7% in all age-groups ept 15–30 years, at which age it was considerably er:

Age-group	*No. of cases*	*Deafness*
0–4	242	9 (3·7%) } (5·0%)
5–14	90	7 (7·7%) }
15–29	220	6 (2·7%)
30–44	88	7 (7·9%)
45–59	46	3 (6·5%)
60 and over	20	1 (5·0%)
Totals	706	33 (4·7%)

The deafness affects the higher pitched tones, including whole range of human speech. Low tones and rations may be perceived but not clearly distinguished. nitus occasionally accompanies the deafness but is usually troublesome. The incidence of deafness has en been estimated at about 2% at the time of discharge om hospital (Harries 1942, Joe 1942, Beeson and terman 1943). This is an underestimate for the llowing reasons: (1) deafness in infant patients may t be detected until the second year of life; and) unilateral deafness may not be detected until some e after the patient's discharge from hospital, unless ch ear of every patient is carefully tested separately fore discharge from hospital. In a follow-up of 1075 cases in the London region Maddock (1943) reported 37 cases (3·4%) of partial or total deafness, and in a similar follow-up in South Wales the figure was 5·5% (Degen 1945). In my series 29 cases of deafness were detected in hospital and 4 cases after discharge, a total incidence of partial, total, unilateral, or bilateral permanent deafness of 4·7%. About half of these cases had total bilateral deafness:

Type of deafness		*No. of cases*
Transient		7 (1·0%)
Permanent:		
Unilateral	partial	6 (0·8%)
,,	complete	5 (0·7%)
Bilateral	partial	6 (0·8%)
,,	complete	16 (2·3%)
Total permanent		33 (4·7%)

ARTHRITIS, BURSITIS, AND TENOSYNOVITIS

There were 33 cases (4·7%) of joint complications in the series. The joints affected were the shoulder, elbow, wrist, small joints of hand, and knee. Occasionally bursæ in the neighbourhood of joints and tendons at the back of the wrists were affected. The synovial fluid was often turbid, but meningococci could not be grown from it owing to efficient chemotherapy. Resolution was nearly always complete in a few weeks, but occasionally knee, elbow, and shoulder arthritis persisted for some months.

CRANIAL-NERVE PARALYSIS

Lower-motor-neurone Type.—Most commonly this paralysis involved the sixth nerve, then the seventh, third, and fourth in that order. It is probably due to pressure of meningeal exudate on the nerves as they emerge from the brain stem. The duration of paralysis varies from a few days to about four months, the average being two to three weeks, and it always clears completely. In the series there were 16 cases of unilateral and 4 of bilateral external-rectus, 11 of facial, 4 of oculomotor, and 1 of superior-oblique paralysis, a total incidence of 5·2% of lower-motor-neurone cranial-nerve palsies.

Upper-motor-neurone Type.—Cranial nerve paresis of this type is occasionally seen in encephalitic cases. It is usually much more transient than the lower-motor-neurone types. In the present series there were 5 such cases of facial paresis, and there were also one or two cases of transient ptosis of doubtful origin.

NEURITIS OR RADICULITIS

Pressure of exudate on spinal nerve-roots occasionally gives rise to flaccid paralysis of single muscles or muscle groups, but no example of this occurred in the series. It has to be distinguished from sciatic palsy due to the injection, through ignorance or error, of irritating material—e.g., sodium sulphapyridine—into the theca. In the early days of sulphonamide therapy this mistake occasionally caused permanent foot-drop.

HEMIPLEGIA, SPASTIC PARALYSIS, AND JACKSONIAN CONVULSIONS

These are usually due to pressure on the cerebral cortex in the early acute stage when purulent exudate is at its maximum, but they may be due to encephalitic lesions. Since efficient chemotherapy has been used they have become relatively rare and usually transient. In the present series there were 10 cases, including 3 of hemiplegia, among 654 recovered cases. In 1 exceptional case which was fatal, hemiplegia was due to focal hæmorrhage in the internal capsule.

THROMBOSIS OF SUPERIOR LONGITUDINAL SINUS

This is a rare and unexpected catastrophe; 1 case occurred in my experience.

The Milroy lectures to the Royal College of Physicians for 1945. Deferred because of the author's service overseas.

not making sufficient effort or were becoming neurotic. When the thyroid gland was exposed at operation, it was found that, though the gland was small, high upper poles were lying behind the larynx and pharynx. Their appearance was similar to that of a retrotracheal nodule as already described.

(4) *Pronounced Exophthalmos* (approaching the malignant type).—This is usually found in people over 35 years of age and is accompanied by œdema of the eyelids. We have given a few of these cases serious trials of thiouracil, but none improved and, as the B.M.R. became less, the exophthalmos increased. In the type of exophthalmos seen in patients under the age of 30 years with Graves's disease the protrusion of the eye subsides equally with the subsidence of the toxic symptoms, whether treated by thiouracil or by surgery.

(5) *Predominance of Heart Symptoms* (e.g., tachycardia and fibrillation).—These are the last symptoms to improve on thio compounds—it may take months, as opposed to the quick results of surgery.

(6) *Depression due to Thyrotoxicosis.*—The thio compounds, like the sulphonamides, are inclined to cause depression in some patients.

(7) *Absence of Facilities for Blood-counts, &c.*—If patients have to come in to a centre where there are such facilities, then the economic question is to be considered, since they have to give up work for a much longer time than has the average surgical case.

We have seen one patient die as a result of thiouracil. She was a woman of 50 sent into the hospital from a country district as an acute cholecystitis. A blood-count showed a complete absence of white cells. It was then discovered that she had been treated for two months with thiouracil for thyrotoxicosis. In spite of all treatment, including parenteral penicillin, she died in three or four days.

INDICATIONS FOR TREATMENT WITH THIOURACIL

The following are indications for the use of thiouracil:

(1) *Young People with Graves's Disease.*—At this age nodulation is only just beginning; therefore difficulties arising from increase in size of the thyroid gland are not common, except in those with high retrolaryngeal upper poles.

(2) *Predominance of Nervous Symptoms except Depression.*—There is no doubt that a quicker improvement of the nervous flushes and excitement takes place with thiouracil compounds than with iodine.

(3) *Elderly people who are grave surgical risks.*

(4) *Recurrent Thyrotoxicosis after Operation.*—These cases often respond quickly to 0·2–0·3 g. of thiouracil daily, but we have had several failures because the swelling of the thyroid remnant has been increased by the administration of thiouracil and caused a choking feeling. (In our method of thyroidectomy a small piece of the posterior part of the thyroid gland is left lying closely along each side of the posterolateral aspect of the trachea.)

Preparation for Operation.—Severe thyrotoxicosis may be benefited by preoperative treatment with thiouracil. As a rough guide it is said that one day of treatment will be needed for each percentage of elevation in the B.M.R. This means that a patient with a B.M.R. of 90% would take 90 days of preparatory treatment and, at the end of that time, would have to have two weeks' treatment with iodine to make the operation less difficult. There is no doubt that a thiouracil-prepared case is more difficult than one which has not been so prepared. The use of iodine makes the gland less vascular and firmer and so easier to operate on. Altogether this subjects the patient to a long period of preparation.

Personally, I can see no advantage over the old iodine preparation, combined with rest and sedatives, which will enable a patient with a B.M.R. of 100% to be ready for operation in 10 days or so.

Two years ago, reporting on the result of treatment of 45 cases with thiouracil, I was able to say that 50% had done well.[1] Since that date 6 of these have relapsed and 3 have been operated on; hence the percentage of recovery of these original cases is now only 35%.

It seems that thiouracil treatment should be continue for a year or even two. All this time the thyroid glan is kept in a state of cellular activity, as shown histological sections. In spite of this activity the thyro gland cannot manufacture its normal hormone; ar this may have harmful results, for Purvis and Guisbach have produced adenocarcinoma of the thyroid gland rats by continued administration of thiourea for t years.

TREATMENT BY SURGERY

Nearly all the failures in all groups were submitt to surgery, making with those operated on without tr of thiouracil over 250 cases. Of the patients und 21 years of age 16 were operated on and only 14 d well. The other 2 were not good results and we given a postoperative course of thiouracil. On this th improved a good deal but are not entirely satisfacto yet. In the age-group 21–45 all the patients operat on did well. Of those aged over 45 all did well exce a woman, aged 70, who had been treated with thioura for over a year.

She had made great improvement, regarded herself cured, and stopped taking the drug. I was asked to her again nine months later. The nodules in the neck h become hard and firm, and she again had thyrotoxico Chiefly because of the hardness of the gland, which suggest a malignant change, operation was advised. She died fr abdominal distension the day after operation. The sectio from this gland were not malignant but showed so thyroiditis.

This was the only death in the series, making t surgical mortality well under $^1/_2$%.

SUMMARY

Of 350 patients with thyrotoxicosis 111 were treat with thiouracil: of those aged under 21 years 10 o of 16 (62%) were improved; of those aged 21–45 yea 29 out of 73 (40%) were improved; and of those ag over 45 years (all with nodular goitre) 11 out of 22 (50 were improved.

Contra-indications to the use of thiouracil are sig of pressure on the airway, toxic nodular goitre, a retr laryngeal upper pole of the thyroid gland, pronounce exophthalmos, predominance of heart symptoms, depre sion due to thyrotoxicosis, and the absence of facilit for blood-counts, &c.

Indications for the use of thiouracil are the youth the patient, predominance of nervous symptoms oth than depression, elderly patients who are grave surgic risks, recurrent thyrotoxicosis after operation, and seve thyrotoxicosis requiring preparation for operation.

Over 250 patients with thyrotoxicosis, including near all those who did not respond sufficiently to thiourac were operated on: of those aged under 21 years 14 ou of 16 did well; of those aged 21–45 years all did wel and of those aged over 45 years all did well except o who died (the only death in the series).

"... The whole world is in a state of unrest: countrie peoples, nations, institutions, are being swept by viole winds; heavy gales are blowing everywhere.... Previous the roots of our being remained steady in the depths ev though the boughs swayed and tossed above. Now we beg to feel that fear-making loosening of roots. It is not to much to say that every institution, every individual is no faced with the challenge 'Look to your roots.' It is then that we will find a new wisdom in the original necessity ou of which our institutions and tradition grow. Problems o Good and Evil, God and Devil could in the days of ou fathers be dealt with in traditional ways, often by traditiona admonitions. Now this does not suffice, and we find it imperative to look into things previously avoided as unwholesome, or even unclean. 'Get thee behind me, Satan'—meaning 'Get you back into the unconscious'—is no longe effective."—Dr. C. M. BARKER, in lecture no. 50 of the Guild of Pastoral Psychology.

ants passed through the intermediate stage known as terior basal meningitis, in which the exudate, after acute stage, collects at the base of the brain and becomes organised. with the formation of adhesions subarachnoid block.

adults, under the same conditions of missed diag- and delayed treatment, hydrocephalus may p, with chronic headache as a symptom. Later, in es, there is a tendency for exudate to collect in the ent dorsal region of the cord, with the formation hesions, pressure on nerve-roots, and possibly plegia. In such a condition a spinal tap may be dry ld a small quantity of xanthochromic cerebrospinal (C.S.F.) of very high protein content—e.g., 1 g. per ml. (Froin's syndrome of spinal block). In my series were 10 (1·4%) cases of hydrocephalus or severe chnoiditis. Of these, 6 were in infants and 4 in adults. n admitted to hospital these patients were all in second or third week of the disease, the diagnosis ing been missed in the early acute stage. Of the ants 3 died, 1 developed chronic hydrocephalus, and ade a perfect recovery. Of the 4 adults 2 died d 2 recovered completely.

Delayed arachnoid clearing without adhesions and hout symptoms—e.g., where the C.S.F. shows a cytosis of 10–30 cells per c.mm. some weeks after acute stage—is of little significance. It normally ompanies resolution in some cases and should be regarded.

RARE COMPLICATIONS

Orchitis and epididymitis are now very rare. I have not n a case. Other rarities are *salpingitis, jaundice,* and *lytic ileus*; 1 case of jaundice and 1 of paralytic s occurred in my series. *Otitis media* is due to dary infection and is rare.

RELAPSES AND RECURRENCES

pse or recrudescence occurring within a few weeks the primary attack was formerly common. With sulphonamide treatment it is now uncommon; occurred in the series.

nd Attacks.—Immunity does not seem to be solid permanent in meningococcal disease; 4 second cks were noted in the series, one, two, three and ty-five years after the first attack.

SEQUELÆ

By far the most common permanent sequela of organic in is deafness. Others include hydrocephalus, blind-, and paralyses of various kinds. The group of called psychiatric sequelæ were intensively studied the late war. They are partly of organic origin but be intensified and fixed by wrong psychiatric hand-, especially in war-time when escape from military vice becomes a strong subconscious motive. The most mon symptom is persistent headache. As a rule this intermittent, lasting a day or two, and followed by mal intervals of a few weeks; the attacks may r for as long as eighteen months. The headache may aggravated by exposure to sunlight or by stooping. gradually clears unless perpetuated by emotional . It may be associated with failure of concentration. kache, insomnia, depression, postural dizziness, ctional ocular symptoms, muscular limb pains, effort mptoms, poor memory, dreams, dyspepsia and vertigo. some cases there is a change in personality from eableness to chronic irritability.

"Many of these symptoms are frankly hysterical in ture, and they are strikingly correlated with predisposition to psychoneurosis, as determined by psychiatric study of the personality. They are only partially correlated with the severity of the acute illness" (Ballard and Miller 1945).

My experience is in agreement with this judgment. These sequelæ are nearly all temporary and disappear within a year or two. Maddock (1943) and Degen (1945) each reported on the after-histories of about 1000 patients discharged from hospital during the war. These patients were visited by nurses, and the symptoms complained of were recorded. In Maddock's series 51 patients recorded as having complaints were ex-patients of the Park Hospital. These were requested to attend for medical examination, and 34 of them did so from some nine months to two and a half years after discharge from the hospital. Of the 34, no sequelæ could at that time be detected in 16, and in a further 7 cases the sequelæ reported were due to causes unconnected with the meningitis. In 2 cases the complaints were "backache" and "weakness of ankle" and appeared to be clearing. Of the remaining 9 cases 8 were deafness and 1 loss of an eye—all certainly due to the meningitis. This small experience fits in with other observations that, within a year or two of the attack of the disease, functional sequelæ have nearly all cleared, and that in well-treated cases there is little residual disability except deafness. However, it was found in both world wars that suggestion by doctors and others plays a significant part in the production and perpetuation of the psychiatric group of sequelæ, and that admission to hospital must for this reason be avoided.

The principal complications in my 706 cases were as follows:

Complication	*No. of cases*
Deafness	33 (*4·6%*)
Arthritis, bursitis, tenosynovitis	33 (*4·6%*)
Lower-motor-neurone paresis:	
III nerve	4 (*0·6%*)
IV ,,	1 (*0·2%*)
VI ,,	20 (*2·5%*)
VII ,,	11 (*1·5%*)
Upper-motor-neurone paresis: VII nerve	5 (*0·7%*)
Spastic paralysis, jacksonian convulsions	7 (*1·0%*)
Hemiplegia	3 (*0·4%*)
Thrombosis of superior longitudinal sinus	1 (*0·2%*)
Iridochoroiditis	2 (*0·3%*)
Panophthalmitis	1 (*0·2%*)
Auricular fibrillation	3 (*0·4%*)
Glycosuria (non-diabetic)	5 (*0·7%*)
Bronchopneumonia	4 (*0·6%*)
Empyema	1 (*0·2%*)
Hydrocephalus, arachnoiditis	10 (*1·4%*)
Herpes febrilis (extensive)	10 (*1·4%*)
Relapse	3 (*0·4%*)
Second attacks	4 (*0·6%*)

Treatment of Ordinary Form

CHEMOTHERAPY

In the ordinary form of the disease the infection is best combated with sulphonamides alone. Penicillin is not required either systemically or intrathecally. Several controlled series have shown that penicillin is inferior to sulphonamides in the treatment of the ordinary form (*Lancet* 1947). The best drugs in my experience are sulphathiazole and sulphadiazine. Some have claimed that sulphanilamide is equally good. I had extensive experience with this drug in 1937 and 1938 and learnt that low dosage with sulphanilamide is much more dangerous than it is with the newer drugs. I have never seen drug-resistant meningococci except where sulphanilamide was used. Moreover, this drug often causes cyanosis and mental confusion. Sulphanilamide should be used when renal blockage is feared (its acetyl derivative is much more soluble in urine than that of other sulphonamides) and either it or 'Sulphamezathine' in congestive heart-failure when adequate fluids cannot be given. A theoretical objection to sulphathiazole, still held in some quarters, is its low concentration in the C.S.F.—15–40% of the blood-level. Many cases in my series, treated with rapid and complete success, had only about 1 mg. per

A girl, aged 4 years, was admitted with a moderate attack of the ordinary form; group-II meningococci were cultivated from the spinal fluid; forty-eight hours after admission, when she seemed much improved and the spinal fluid was sterile, she had a sudden attack of vomiting and restlessness; rapid respirations and coma developed, and she died two days later.

At necropsy there was a clearing meningitis, thrombosis of the superior longitudinal sinus, and hæmorrhage into the left frontal lobe. The source of the thrombosis was presumed to be the meningococcal vascular lesion.

OPHTHALMIA

Hyperæmia of the conjunctiva with photophobia often accompanies meningococcal meningitis.

Purulent conjunctivitis may occur as a presenting symptom of meningococcal disease in otherwise healthy subjects or as a complication.

Iridochoroiditis is a more frequent complication. It was noted in 7 cases (1%) in the series. In a woman of middle age the condition progressed rapidly to panophthalmitis, with loss of the eye. In another case pus was observed for two or three days in the anterior chamber, but complete recovery ensued. In 2 young children with iridochoroiditis in the early acute stage of the disease the media were semi-opaque, with 100% loss of light reflex. These 3 cases cleared completely under sulphathiazole treatment.

Blindness may result from (1) iridochoroiditis developing to panophthalmitis, (2) acute optic atrophy apparently associated with pressure of meningeal exudate at the optic chiasma, (3) the optic atrophy of chronic hydrocephalus, or (4) a central lesion in the occipital lobe. All forms are now rare. The incidence of permanent blindness in Beeson and Westerman's (1943) analysis of 3575 case-records was 0·11% and in my series 0·14%.

RETENTION OF URINE

This often presents a considerable problem, especially in men. Restlessness and a tendency to get out of bed may be partly due to a subconscious desire to urinate. Retention of urine soon leads to symptoms of uræmia. The blood-urea should be frequently tested until urine is passed freely. Uræmic coma may tip the scale against the survival of elderly patients. An indwelling catheter is a good precaution against uræmia in difficult cases.

DEHYDRATION

This tends to occur in children and delirious patients owing to the difficulty in giving fluids. Vomiting increases the tendency, and this was a particular danger when sulphapyridine was used in treatment.

CARDIAC COMPLICATIONS

Toxic myocardium is always present in some degree in the acute stage. It was particularly evident as a direct effect of the toxæmia in 4 cases (0·6%) of my series. These were in young people aged 2, 6, 16, and 24 years. They all showed evidence of cardiac dilatation. In 3 cases the auricles were fibrillating for two or three days, and in 1 patient aged 6 years a well-marked *bruit de galop* persisted for three days. All 3 cases rapidly recovered after the infection had been overcome by chemotherapy. In elderly people with myocardial degeneration the toxic effect of the acute disease on the myocardium is less readily assessed.

Pericarditis should be carefully looked for; it may be found unexpectedly at necropsy. *Endocarditis* is rare.

GLYCOSURIA

Pressure of exudate on the floor of the fourth ventricle may occasionally cause glycosuria, which may be associated with severe acetonuria and even coma and has then to be distinguished from concurrent true diabetic coma. In diabetic coma a history of diabe and the presence of dehydration, low ocular tension, blood-pressure, high blood-sugar and well-marked ket uria are significant points. In my series 5 cases glycosuria and 1 of concurrent diabetic coma were not

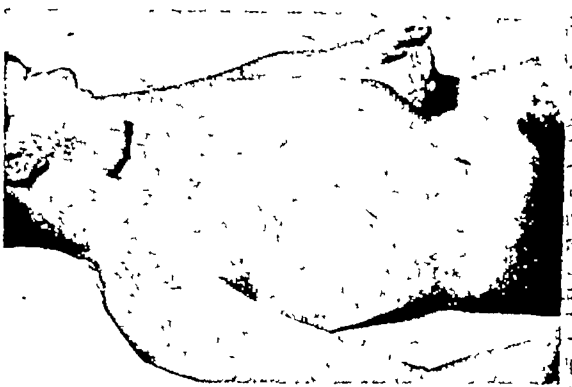

Fig. 11—Extensive herpes febrilis on face, left thumb, and left [illegible] groin, probably spread by contact.

HERPES FEBRILIS

This is a frequent accompaniment, usually from t fourth or fifth day of the disease; it is usually confin to the labial region but is occasionally more extensi It may involve the face, palate, hand, arm, neck, a even parts of the trunk and lower limbs. This extens herpes is sometimes regarded as herpes zoster, but it very exceptional for it to correspond exactly to distribution of a particular nerve. Rolleston (19 referred to it as herpes of zoster type. It is unlikely t the chickenpox virus, which is the usual cause of her zoster, would often accompany meningococcal dise whereas the virus of herpes febrilis is well known to associated with meningococcal, pneumococcal, and respiratory infections. Of 10 cases of extensive her observed in my series the sites affected were all with easy reach of the patient's hands. In 2 cases the patient thumbs were affected besides the face and trunk or In no case did the area covered by the lesions corresp exactly to the distribution of a cutaneous nerve or nerv When herpes in this disease extends beyond the lab region it may have been spread to the new site by t patient's hands (fig. 11). In one of my cases, a vi of herpes febrilis type was isolated from the vesicul fluid by Dr. F. O. McCallum.

ULCERS OF SKIN AND SUBCUTANEOUS TISSUE

These occasionally result from the breaking down *massive purpuric lesions* owing to the growth of mening cocci within those lesions. If such lesions beco secondarily infected, considerable scarring, even of keloid nature, may result.

RESPIRATORY COMPLICATIONS

Bronchopneumonia is a not uncommon associat condition, especially in infants. The combination is ve serious. Some cases are meningococcal in origin, b most are probably due to a secondary pneumococ or hæmolytic streptococcal infection. Several of m cases of concurrent pneumonia and meningitis were infants aged 2 or 3 months, who appeared to be save by the combined use of chemotherapy and the oxyg tent.

Pleurisy is very rare. *Empyema* was found in 1 case.

HYDROCEPHALUS AND ARACHNOIDITIS

These result from subarachnoidal adhesions due t insufficient or delayed therapy in the acute stag Formerly this was relatively common in infants. Suc wing case, however, only temporary improvement obtained.

A woman of 31 was admitted on the fifteenth day of disease a fortnight's history of intermittent headache, backache, ting, and slight stiffness of the neck, during most of time she had been ambulant. The relatively mild ptoms had misled the doctor in attendance, and the nosis of meningitis was overlooked.

On admission she was conscious and rational, with pyrexia, neck, slight upper-neurone left facial paresis, unequal s, transient diplopia, right knee-jerk diminished, fundi mal, C.S.F. scanty, xanthochromic, cells 309 per c.mm. nonuclears 76%), chlorides 590, *protein* 1150 *mg. per ml.* Colloidal gold early mid-zone curve; Wassermann tion weak positive (negative in blood); a few meningo-ci seen in films but none cultured. Complement-fixation for meningococcal infection positive (Dr. R. Cruickshank) te-cell count 14,600 per.c.mm. (polymorphs 84%).

Treatment.—Sulphathiazole 9 g. daily, gradually reduced 4 g. daily, for eight days.

Course.—Patient improved gradually but had severe chronic dache in left frontal region for many weeks, with vomiting times. Lumbar puncture on several occasions produced y a few ml. of xanthochromic and highly proteinous sterile id., and after three months no fluid. Cisternal puncture a dry tap on two occasions. Ventricular puncture after months gave a clear fluid from each ventricle at normal ssure, but this did not relieve headache at once. Headache ntaneously cleared, however, seven days after the second tricular puncture, three and a half months after admission. ee weeks later, spastic paraplegia with some sensation s in right leg. Six weeks later, spastic paraplegia in both s, feeling of a band round waist, tickle sensation in this n lost, pinprick and vibration sense lost in both limbs. gnosed as compression paraplegia from D5 to D12.

Operation (Mr. Dickson Wright).—Cisternal puncture having this time yielded fluid, laminectomy from D3 to D12 was ne, and adhesions were freed. As a result patient could ve her legs, but recovery was incomplete. Cisternal Lipiodol’ now revealed lower limit of fluid to be C2 vertebra. injection of lipiodol, left frontal headache and vomiting red, and many ventricular punctures revealed a return of hydrocephalus and did not relieve it.

d Operation.—Foramen of Majendie found completely with thin diaphonous adhesions; double hydro- Foramen was cleared. Four days after the second tion patient died of œdema of medulla. Though the logical signs pointed to obstruction at about D5, there e dense adhesions from C2 to D12, as well as in the terior fossa at the foramen of Majendie.

PROPHYLAXIS

Meningococcal infection is endemic in most countries. never dies out completely but persists to a variable tent in the nasopharynx of carriers, and in abortive, ld, and other cases at all times. It cannot therefore eliminated by the isolation of clinical cases. Never-theless, with few exceptions, patients with clinical ningococcosis should be removed to hospital for con-mation of diagnosis and effective treatment. Prophy-xis among large bodies of colonial troops by injection meningococcal vaccines was tried in presulphonamide ys without convincing success, and a skin test for munity was also in the experimental stage. These asures have been superseded by mass prophylaxis ith sulphonamides.

Carriers.—The complexity of the carrier state was monstrated by investigations in the great semi-isolated U.S.A. military camps during the war. Phair et al. (1944) howed, in one infected camp, that when swabs from 100 oldiers were cultured on multiple plates at intervals during ten weeks, 91% were found positive at one time r another, more than half of them harbouring two or more specific strains. It is now clear that the carrier-rate of a group cannot be adequately determined by single cultures, and that the carrier state of a group is a complex ever changing pattern. It is therefore a vain endeavour to attempt to isolate carriers.

Mass prophylaxis by administration of sulphonamide simultaneously to all members of an infected semi-isolated group does eliminate carriers as well as clinical cases to a very large extent. This method has been used with success to break an epidemic in such semi-closed communities as (1) a children's residential home (Meehan and Merrilees 1940); (2) large military camps (Painton 1944); and even (3) a city of 100,000 inhabitants set in mountainous surroundings. There is evidence that a single dose of sulphadiazine 2 g. (or its equivalent) given simultaneously to every member of the selected community will achieve this purpose (Phair et al. 1944). The carrier-rate is reduced to a very low figure—e.g., 5–10%—for three weeks or more and then gradually rises, but by the time it does so the occurrence of clinical cases has stopped. This method has little application, however, to the infected individual household of an ordinary civilian community, since its members, unless isolated from the rest of the community, would quickly become reinfected.

Quarantine of contacts is useless and an unnecessary waste of time. Prophylactic sprays and douches are also useless and may be harmful. Fomites, unless very recently contaminated, do not convey the infection.

The convalescent patient now rarely harbours meningococci, since the sulphonamide treatment destroys them. The practice of swabbing his nasopharynx before release from hospital has been generally discontinued as not worth while.

The routine use of masks by attendants on patients in the acute stage is generally impracticable and is unnecessary, since direct infection is extremely rare. Their occasional use for a short time is advisable when an attendant is exposed to gross infection—e.g., in struggling with a delirious patient.

It is a great pleasure to acknowledge the valuable assistance I have received from many past and present members of the medical and nursing staff of Park Hospital, and of the medical and technical staff of the Southern Group Laboratory.

100 ml. of free sulphathiazole in the C.S.F. during the first three days of treatment and about half this concentration thereafter. Such low concentrations were never ineffective, provided the patient was not moribund or beyond the reach of drugs.

The scale of dosage used throughout the series was that recommended by the Medical Research Council (1943) which is now standard practice in most British hospitals. Important points are that the dosage for infants of any age over 2 months during the first three or four days of treatment should never be less than 3 g. daily, and for adults 9 g. daily. It is well to begin with a "loading" intravenous dose in all severe cases. The best drug for intravenous or intramuscular injection is 'Soluthiazole' (M. & B.), which is nearly neutral (about pH7) but not quite isotonic. It is unirritating and has completely superseded the highly alkaline sodium salts. Sulphathiazole or sulphadiazine by mouth should always be given in an alkaline mixture containing the equivalent of gr. 20 each of sodium citrate and sodium bicarbonate to keep the urine alkaline, and at least 5 pints of fluids for an adult should be given daily.

OTHER TREATMENT

Spinal drainage, other than that obtained by the first lumbar puncture, is rarely necessary. The C.S.F. is nearly always sterile twelve to forty-eight hours after efficient sulphonamide therapy has been begun, and, with the infection overcome, the pressure rapidly becomes normal.

Sedation.—It is well to avoid morphine even in violent delirium since, among other undesirable effects, it increases the tendency to retention of urine and so to the deposition of crystals in the renal tubules and pelvis. 'Sodium amytal' gr. 3 combined with paraldehyde min. 120 is a good sedative hypnotic. Paraldehyde alone is seldom effective, unless as much as 6 drachms is given to an adult. A useful barbiturate sedative-hypnotic is 'Somnifaine' (Roche), of which repeated doses of 2 ml. may be given intramuscularly or by mouth.

Restraint.—A bed with cot sides is most useful for delirious patients. Restlessness and getting out of bed by unconscious patients is often due to a desire to urinate. This should be anticipated.

Urinary Tract.—If there is retention of urine, the catheter should be used before the bladder is greatly overdistended. If retention persists, a self-retaining catheter should be passed, or an ordinary one tied in for a few days. The chemotherapy will usually control catheter infection, provided reasonable aseptic precautions are taken. Hæmaturia or oliguria is rare when sulphonamides are given with alkali; but, if they appear, the drug must be promptly changed or stopped, and warmth or diathermy applied to the loins. Fluids must be pushed, unless there is threatened anuria, which should be promptly treated by ureteric catheterisation and wash-out.

Glycosuria may be ignored, unless it is due to diabetes, when the insulin intake must be regulated.

Concurrent pneumonia is not uncommon in infants and is very serious. The oxygen tent is very helpful in such cases.

Special Syndromes

FULMINATING SEPTICÆMIA OF ADRENAL AND MIXED TYPES

This is a medical emergency requiring immediate multiple measures.

(*a*) Combat the infection with sulphathiazole or sulphadiazine combined with systemic penicillin in high dosage.

(*b*) Combat shock by adrenal replacement therapy, especially adrenal cortical extract—e.g., 'Eucortone' 5 ml. intramuscularly or more every four hours; plasma intravenously seems also to be indicated in the present state of our knowledge.

(*c*) Combat anoxæmia with oxygen, especially the oxyg tent for a child.

(*d*) Combat any special complications—e.g., hyperg cæmia, with insulin, dehydration with salines, &c.

Combating the infection is the most important measu Both adrenal replacement and plasma for shock syn toms should at present be used, though the exact va of each cannot easily be assessed.

It is of the utmost importance to establish the diagn of the syndrome early by careful examination, includ blood-pressure readings, and then to initiate full tre ment without delay. A fair proportion of lives can saved, at least in the pure adrenal type. In the mi type the same measures are applicable, but, in additi 20 ml. or more of 50% glucose may be injected int venously in an attempt to relieve the œdema of brain and the intracranial pressure.

FULMINATING SEPTICÆMIA OF ENCEPHALITIC TYPE

(*a*) Combat the infection with intravenous and in muscular soluthiazole and penicillin.

(*b*) Feed the patient by nasal tube.

(*c*) Combat dehydration with parenteral or rectal saline

(*d*) Combat the œdema of the brain with intrave hypertonic glucose.

ACUTE DIFFUSE ENCEPHALITIC SYNDROME

(*a*) Combat the infection with intravenous and in muscular soluthiazole and penicillin until consciousnes restored, and thereafter with sulphonamides by mouth.

(*b*) Feed the patient by nasal tube.

(*c*) Correct dehydration.

(*d*) Give 20 ml. of 50% glucose intravenously to re œdema of the brain, and repeat as necessary.

This last measure is sometimes dramatically succes in this syndrome, but sometimes it appears to h no effect.

A man of 62, after thirty-six hours' deep coma, beca conscious within a few minutes of the injection of the hyp tonic glucose. The lucid interval lasted only 5 min., which he relapsed into deep coma within the next half-h Repetition of the dose next morning had a similar dram effect, but this time he remained conscious and slo recovered.

CHRONIC FORM

Hydrocephalus.—Ventricular drainage by punct should be tried, but it is rarely successful in re-establish the flow of C.S.F. In infants and young children hyd cephalus sometimes clears spontaneously after so months, even when temporary blindness seems to h been present. If the condition has not cleared in months and the head is enlarging, neurosurgery m possibly be able to re-establish drainage, not with considerable operative risk. In one of my cases anterior wall of the third ventricle was removed provide an outlet for the retained fluid to flow over surface of the brain in the subdural space. No perman benefit, however, resulted from this operation. I indebted to Mr. Dickson Wright for information Hyndman's operation (ventriculocisternostomy) whi appears to be promising. A communication can be ma from ventricle to subarachnoid space by disrupting pia-arachnoid and ependyma of the choroid plex This provides an effective means of shunting the circul tion of the fluid from the ventricle through the su arachnoid spaces of the tela choroidea to the basal cistern which, fortunately, are rarely obliterated by the chron inflammatory process (Hyndman 1946).

Paraplegia.—Where there is compression paraplegia neurosurgeons have had a few successes with an extensi laminectomy and freeing of the adhesions. In th

DISCUSSION

It is therefore clear, nor is it surprising, that organisms can readily grow through a dressing steeped in plasma or broth, and it seems a safe assumption that the same will happen if the nutrient fluid is the normal exudate from a burned surface, since small inocula of these same organisms—hæmolytic streptococcus, staphylococcus, Proteus, and *Ps. pyocyanea*—have been found to grow freely in such exudate (blister fluid).

How often such an ingrowth of organisms does in fact occur through dressings soaked in vivo with serous exudate or blood we do not know. It will always be difficult to prove. It probably happened in the case of A.B., and it may well have been responsible for a number of other added infections by *Ps. pyocyanea* which developed between the first and second dressings of such burns (the period of maximal exudation) during the latter part of 1947 (Colebrook et al. 1948). It may also have been responsible for many of the early infections of burns by hæmolytic streptococci reported by Cruickshank (1935) from the burns wards of the Glasgow Royal Infirmary and noted by Stuart in the same wards during 1941 (see Colebrook et al. 1945). In a ward with many other infections by that organism (from which it may be disseminated by the air) the passage of hæmolytic streptococci through intact but soaked dressings would be particularly liable to occur because of the readiness with which it can multiply in fresh wound exudate from the smallest implant (Wright 1915, Wright et al. 1918).

Quite apart from burns, the tendency for dressings to become soaked after operations is well known to surgeons and ward sisters. The possibility of growth of organisms through such dressings should always be borne in mind. The best way to prevent it is not yet clear. Insertion of a thin plastic sheet under the outer bandage should be effective in many cases, but the use of some of these materials has certain disadvantages. Cellophane, for instance, is difficult to apply because of its inelasticity and its liability to tear; the bandages over it also tend to slip on the smooth surface. Other plastic films with better mechanical properties, such as polythene, are impervious to water vapour as well as to water; and, if the dressing is completely enclosed by them and is bandaged firmly to the skin all round, the underlying wound becomes sodden and healing may be retarded. The ideal material, besides being flexible and strong, would be pervious to water vapour but not to liquids or to bacteria. Such a material (a derivative of 'Nylon') has already been produced in small quantities, and some experimental results obtained with it have been described by Bull et al. (1948). It is hoped that larger quantities of this plastic will soon be available for more extended trials.

SUMMARY

The possibility that wound pathogens can readily "grow through" an intact dressing when this becomes soaked with exudates has been investigated.

A model wound was constructed and covered with the usual gauze, wool, and bandages. After repeated instillation of sterile serous fluid into the wound till the outer bandage was just moist, *Ps. pyocyanea* or other wound pathogens were brought into contact with the outer bandage and the whole was incubated. Motile organisms such as *Ps. pyocyanea* and *Proteus* invariably passed through to the "wound" within a few hours; hæmolytic streptococci and staphylococci passed through a little more slowly.

It is suggested that some of the hospital cross-infections of burns and scalds (which frequently weep copiously during the first few days), and probably also of other open wounds whose dressings become soaked, may arise in this way.

A sheet of cellophane inserted in the dressing prevents the ingrowth of organisms, but is not the ideal barrier. A flexible and strong plastic film which is pervious to water vapour but impervious to bacteria is under trial.

A METHOD OF TESTING ANALGESICS IN MAN

A. J. H. HEWER
M.B. Lond., D.A.
RESEARCH ANÆSTHETIST

C. A. KEELE
M.D. Lond., F.R.C.P.
LECTURER IN PHARMACOLOGY

MIDDLESEX HOSPITAL MEDICAL SCHOOL, LONDON

THE usual methods of testing analgesics are based on measurements of the threshold intensity of some stimulus required to elicit pain; but analgesics are mostly used to relieve existing pain. Since the presence of pain may greatly reduce the threshold-raising action of such drugs (Hardy et al. 1940), measurements of thresholds may not correlate with the ability of a drug to relieve pain associated with disease. Further, such drugs might act differently on superficial pain (produced in most threshold studies) than in deep pain.

We have tested the power of analgesics to relieve pain experimentally induced by the contraction of ischæmic muscles. Harrison and Bigelow (1943) noted the effects of analgesics on the number of ischæmic muscular contractions required to produce pain, but we have tested the effectiveness of these drugs in the relief of existent pain of ischæmic origin. Our method (Hewer and Keele 1947) therefore lies somewhere between the usual threshold studies and clinical observations on the effectiveness of analgesics. It is illustrated by tests on different groups of analgesics.

Four normal persons were the subjects of our experiments: two medical students (R. M. L. D., aged 20, and J. W. M., aged 19) and ourselves (aged 27 and 41). The tests were usually performed in the late afternoon, with the subject lying quietly on a couch.

PRODUCTION OF ISCHÆMIC MUSCLE PAIN

After a preliminary rest of 5–10 min. a sphygmomanometer cuff was applied to the upper arm and inflated rapidly to 220–230 mm. Hg to cut off the circulation to the arm distal to the cuff. The hand and forearm muscles were next exercised by rhythmically compressing a disconnected sphygmomanometer bulb (to provide a constant resistance against each contraction). After 30–45 such contractions an aching pain usually developed in the flexor muscles in the forearm, and sometimes also in the muscles of the hand. When 50–60 contractions had been completed, there was slight or moderate pain in the forearm muscles. The contractions were then stopped, and the arm was rested with the ischæmia still maintained. At first the pain present decreased, sometimes to zero, and tingling was felt. After 1–3 min., with the arm still at rest, the pain returned and began to build up steadily, until after 8–15 min. (the speed of development of the pain depending on the number of contractions, room temperature, and perhaps other factors) the pain became intolerable. The cuff was then deflated, and the pain disappeared within a few seconds.

At first it was easy to distinguish 5 grades of pain: slight, moderate, severe, very severe, and intolerable. With further experience it was easy to distinguish intermediate grades of intensity of pain, and for convenience the pain intensity has been described in units from 1 to 10.

INFECTION THROUGH SOAKED DRESSINGS

LEONARD COLEBROOK
M.B. Lond., F.R.C.O.G., F.R.S.
MEMBER OF SCIENTIFIC STAFF, MEDICAL RESEARCH COUNCIL

A. M. HOOD
TECHNICIAN

From the Medical Research Council Burns Unit, Birmingham Accident Hospital

IN 1943 Owens, in a paper on the use of pressure dressings in the treatment of burns and other wounds, reported that " outside contamination can reach a wound through the entire thickness of a dressing." That conclusion was based on in-vitro experiments with artificial " wounds " which showed that " it was possible to draw organisms through as many as 64 thicknesses of gauze from the outside." Other experiments showed that a layer of 'Cellophane' interposed between the moistened dressings and the contaminant effectively barred the passage of the organisms. (It may well be that this passage of organisms through a dressing from the outside was recognised during the Listerian era, and that the impregnation of the dressing-materials with antiseptics —e.g., mercuric cyanide—was partly designed to prevent it, but we are not familiar with any experimental work on the subject.)

Owens's work did not come to our notice until 1947, after we had carried out similar in-vitro experiments which are briefly reported here. We became interested in the subject in the following circumstances:

A.B., a man with severe electric burns of both hands and forearms, received the standard plenary dressing within two hours of his accident. Swabs from the hands were examined *before they were cleaned and did not grow Ps. pyocyanea or* any other pathogen. The plenary dressing consisted of thorough cleaning with cetrimide ('Cetavlon') solution, a generous application of cream containing penicillin 200 units per g. and sulphathiazole 3%, and then plenty of sterile gauze and wool, the whole carefully fixed with many crêpe bandages under mild pressure, completely enclosing both limbs to well above the burned areas. This dressing was done under very strict aseptic precaution in the room used exclusively for the first dressing of fresh burns. During the previous twelve months there had been no instance of infection of a fresh burn referable to infection in this room.

As often happens with severe burns, the dressings and bandages over the dependent parts became soaked with serous exudate, and according to custom these dressings were " packed " with more sterile wool and more crêpe bandages. The original dressings were not disturbed in any way, because they were in good order and fitting snugly to the limbs. On the fifth day the characteristic blue-green staining of *Ps. pyocyanea* was noticed on the outer bandage of one arm. Re-dressing next day revealed the presence of *Ps. pyocyanea* on both hands.

Reflection on the possible source of this infection suggested at once a connexion with two other men in the same ward (one only 12–15 ft. away) with a similar infection. Both of these had old burns already infected on admission (4 months in one case and 14 days in the other). They were confined to bed, but there was clearly the possibility that the organisms had been transmitted from them to A.B. either by the air or by indirect contact —e.g., by nurses' hands or clothing during the process of making beds. That at once suggested the question: could the *Ps. pyocyanea* grow through the intact dressings of A.B. when they were soaked with serous exudate?

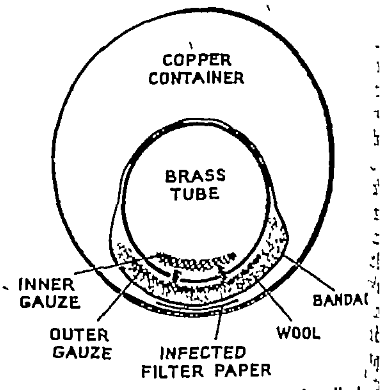
EXPERIMENTS

To investigate this possibility an experimental " wound " was devised and used as follows:

Several holes were drilled near one end of a piece of brass tubing 8 in. long and 2 in. in diameter. Through these holes wicks of gauze were carried to assist the seepage of flu from a loose piece of gauze placed on the inside of the tu (simulating the " weeping " tissues of a wound) to the gau wool, and bandages wrapped round the outside (see figur The tubing with its " wound " was then placed horizontall resting on a piece of filter paper (which would later rece the inoculum of organisms), inside a sealed copper contain and sterilised in the autoclave.

For each experiment an artificial " wound " of t kind in its container was placed horizontally in t incubator, and the inner gauze was first primed by series of additions of sterile fluid until, after a few hou the outer bandage was just moist. Since blister flu from burned patients was not available in sufficie quantity, the fluid used for most of the tests was dri plasma dissolved in nutrient broth—to simulate t exudate from burned surfaces.

As soon as the outer bandage had become moist (t filter paper helped to detect this), its sterility, as well that of the inner gauze, was checked by the usual swab examination, and the bandage was then infected by pipetting about 1 ml. of a thousandfold diluted culture of *Ps. pyocyanea* or other organism on to the filter paper. The whole was then reincubated on its side, and further bacteriological tests were made at intervals, both fro the inner gauze and from the bandage. If necessar fresh supplies of sterile fluid were added to the inn gauze from time to time to keep it moist, with appropri precautions against introducing any infection.



Apparatus used in experiment describ text.

RESULTS

The results were briefly as follows:

Organism and number of strains tested	*Interval between infection outer bandage and recovery of organism from inner gauz*
Ps. pyocyanea (9)	Varied from 4 to 48 hr.
Proteus (4)	" " 18 to 42 "
Staph. aureus (4)..	42 hr.
Diphtheroid bacillus (1) ..	42 hr.
Hæmolytic streptococcus (3)* ..	Varied from 24 to 48 hr
Coliform bacillus (1)	42 hr.

* For these tests it was necessary to use a silver-plated tube an aluminium container, because the copper and brass kill the organisms.

Other tests showed:

(1) That a plaster-of-paris shell over the bandag did not interfere with the ingrowing of the organism (*Ps. pyocyanea* grew through in 86–110 hours, an *Proteus* in 42 hours.)

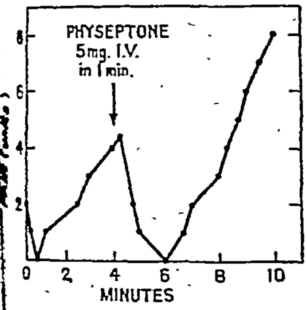
(2) A sheet of cellophane (*supplied by British Cello*phane Co. with the designation P.T.300) interpose between the wool and the bandages did not allow th passage of organisms (6 tests).

(3) A thin sheet of 'Polythene' was also an effectiv barrier.

(4) When the outermost layer of plasma-soaked dressing consisted of many layers of mercuric-cyanide gauze, *Ps. pyocyanea* and *Proteus* and *Staph. aureus* grew through, but not hæmolytic streptococcus, which seemed to be killed off by the cyanide.

the period of testing, the response to a previously determined threshold dose of another drug was usually retested to check the subject's sensitivity.

For example, with subject C. A. K. 0·2 mg. of C.B.11 had no effect, but 0·3 mg. reduced the pain intensity from 4 to 2 units. The threshold dose was taken as 0·25 mg. In other instances the subject's response was of a border-line character, a sort of plateau effect in which the pain curve was just affected. The dose which produced such a response was accepted as the threshold value.



1—Analgesic action of physeptone on ischæmic muscular pain in forearm (contractions) in subject J. W. M.

Threshold determinations gave different results in the three persons studied. The threshold doses found for several drugs were as follows:

Drug	*C. A. K.*	*J. W. M.*	*R. M. L. D.*
Morphine	0·002 mg.	0·1 mg.	0·35 mg.
Pethidine	7·5 mg.	1 mg.	7·5 mg.
Physeptone	0·25 mg.	0·1 mg.	0·3 mg.
C.B.11	0·25 mg.	0·01 mg.	0·4 mg.
Amidone	0·3 mg.	—	—
Hoechst 10582 ..	0·4 mg.	—	—

Thus in subject C. A. K. physeptone and C.B.11 were both [illegible] times as potent as pethidine (the action of morphine was exceptional in this person and is discussed below). In subject J. W. M. morphine and physeptone were both 10 times as potent as pethidine, but were only $^1/_{10}$ as powerful as C.B.11. In subject R. M. L. D. morphine, physeptone, and C.B.11 were about equianalgesic and were 20–25 times more potent than pethidine.

These results may be compared with the figures obtained by Thorp et al. (1947) in experiments on analgesia in rats, in which morphine and physeptone were equally active and about 10 times as potent as pethidine.

We think that individual variations in sensitivity to analgesics are important. Subject J. W. M. was always more responsive to analgesic drugs than subject R. M. L. D. This difference was seen at all dosage levels but was most clearly shown in the threshold measurements. Subject C. A. K. closely resembled subject R. M. L. D. except in his response to morphine. These differences could hardly be attributed solely to differences in body-weight (J. W. M. weighed 11 st. 1 lb., R. M. L. D. 13 st., and C. A. K. 13 st. 4 lb.).

It is therefore obvious that clinical differences in response to analgesics can, at least in part, be ascribed to differences in sensitivity towards them. Since in our experiments the drugs were given intravenously, the differences in sensitivity cannot be due to variable absorption and must therefore represent true differences in analgesic potency. In patients variable absorption from the gut or from the site of injection will contribute other possibilities for variation in response.

CHANGES IN THRESHOLD WITH TIME

We have already pointed out that the threshold should be determined in a short time. The reason for this precaution is that the threshold may change after several months. It would perhaps be generally expected, from the well-known development of tolerance to morphine, that the threshold would rise with the regular performance of these analgesic tests, but the exact opposite was invariably found.

For example, on June 12, 1947, in subject R. M. L. D. the threshold dose of physeptone was 2·5 mg., whereas on Jan. 7, 1948, it was 0·4 mg. Threshold values were not usually determined in the earlier part of our work; hence precise differences in sensitivity cannot be stated, but the responses to supraliminal doses undoubtedly increased with time. Thus in subject J. W. M. the initial response to 1 mg. of C.B.11 was a reduction of pain from 5 to 2 units; this same response later was given to 0·1 mg. of C.B.11.

In general the increase in sensitivity appeared to be about equal for all the drugs studied, and was probably due, *at least in part, to the acquisition of greater skill* in recognising small changes in pain intensity, but we feel that some true increase in sensitivity must also have developed.

In subject C. A. K. an extraordinary increase in sensitivity to morphine developed. In May and June, 1947, the effect of 5·0 and 7·5 mg. was to reduce the pain from 4 units to 1 unit and from 4 units to 0 respectively. These doses produced a definite subjective feeling of respiratory depression and a characteristic occipital headache. The reaction was rather unpleasant at first but was followed by euphoria. On Oct. 24, 1947, it was intended to repeat the 5 mg. dose to see how far the response had changed. When only 2·5 mg. of morphine had been given in $^1/_2$ min., the effects developed very suddenly and were *much greater in all respects than with 7·5 mg. of* morphine five months earlier. Subsequently 0·3 mg. produced an effect definitely greater than did the original 7·5 mg. dose, and later the threshold dose was about 0·002 mg.

Such an increase in sensitivity (about a thousandfold) might suggest an allergic response; but, unlike such a reaction, the hypersensitivity concerned all the pharmacological effects originally elicited by the larger doses. Analgesia, respiratory depression, and occipital headache were about equally intensified. The threshold dose of morphine in J. W. M. was 0·1 mg., and in R. M. L. D. 0·35 mg. The cause of this remarkable sensitisation is not clear, but it might be related to the intravenous route of administration.

ANÆSTHETIC GASES

The analgesic actions of nitrous oxide and cyclopropane were easily demonstrated by the ischæmic-pain method.

Nitrous oxide was given in concentrations of 10–40% in oxygen, the proportions being measured with a rotameter. The ischæmic pain was allowed to develop till the intensity had reached 4 or 5 units, when the gas was inhaled.

A typical result, in subject R. M. L. D., is shown in fig. 4, where inhalation of 20% nitrous oxide and 80% oxygen reduced the pain from 4 units to 1 unit and greatly delayed the increase in pain intensity which would normally have been expected.

In subject J. W. M. the following results were obtained:

Nitrous oxide	*Oxygen*	*Result*
10% ..	90% ..	No effect on pain
15% ..	85% ..	Pain fell from 5→3 units
20% ..	80% ..	„ „ „ 5→1 unit
30% ..	70% ..	„ „ „ 5→1 „
40% ..	60% ..	„ „ „ 5→0 „

Minnitt's apparatus was also tested for its effect on ischæmic muscle pain, 45% nitrous oxide and 55% air

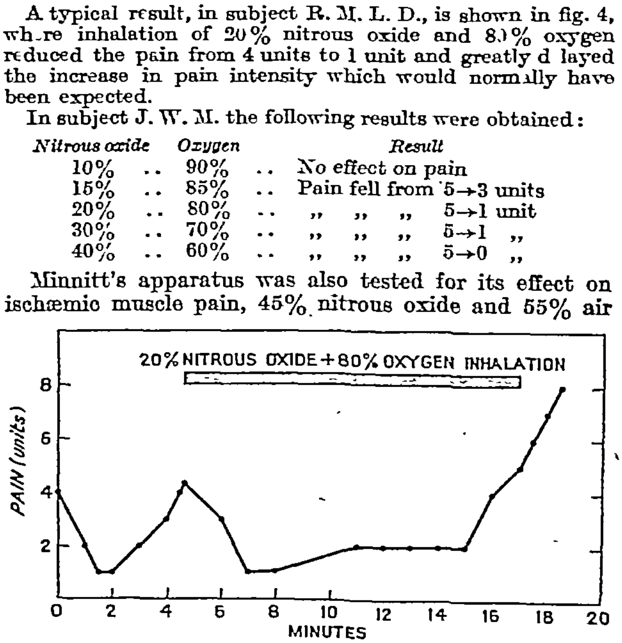


Fig. 4—Analgesic action of nitrous oxide on ischæmic muscular pain in forearm (55 contractions) in subject R. M. L. D.

TESTS OF ANALGESICS

In testing the effects of analgesics the pain was allowed to reach a value of 4–5 units. The drug to be tested was then administered—gases by inhalation, and other drugs by intravenous injection. The gases studied were nitrous oxide and cyclopropane. Nitrous oxide was given in concentrations of 10–40% in oxygen, and cyclopropane in concentrations of 2–3% in oxygen. The proportions of the gases in oxygen were measured with a 'Rotameter,' and the rate of flow was kept fast enough to prevent rebreathing.

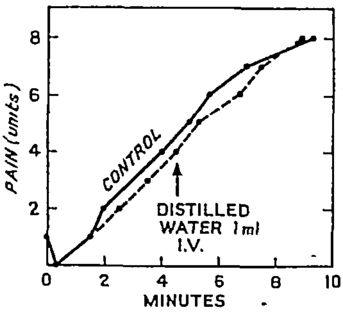

Fig. 1—Effect of injection of distilled water on ischæmic muscular pain in forearm after 55 contractions in subject J. W. M. compared with increase of pain without any injection. Note similarity of curves.

The analgesics given by intravenous injection were as follows:

(1) Morphine (sulphate or hydrochloride).
(2) Pethidine hydrochloride.
(3) *dl*-2-dimethylamino-4 : 4-diphenyl-heptan-5-one hydrochloride ('Physeptone,' 'Amidone,' 'Miadone,' 'Hoechst 10820').
(4) *dl*-1-dimethylamino-3 : 3-diphenyl-hexan-4-one hydrochloride ('Hoechst 10582').
(5) *dl*-2-dimethylaminomethyl-3 : 3-diphenyl-hexan-4-one hydrochloride ('Isoamidone').
(6) *dl*-2-1'morpholino-4 : 4-diphenyl-heptan-5-one hydrochloride ('C.B.11').
(7) Procaine hydrochloride.
(8) Thiopentone soluble.
(9) 'Benadryl' hydrochloride.
(10) N-p-methoxybenzyl-N-dimethylaminoethyl-2-amino-pyridine maleate ('Neoantergan,' 'Anthisan,' pyranisamine maleate).
(11) N-phenyl-N-benzyl-2-methylimidazoline ('Antistin').
(12) Tetraethylammonium bromide (T.E.A.B.).

When morphine, pethidine, and physeptone were given in larger doses, the rate of intravenous injection was 5 mg. per min. for morphine and physeptone, and 50 mg. per min. for pethidine. The maximal doses of morphine, physeptone, and pethidine were 7·5 mg., 7·5 mg., and 75·0 mg. respectively. When the duration of injection was varied with the dose, the needle was kept in the vein for the maximal period of 1½ min., so that the subject could not guess the size of the injected dose from the duration of its administration. Later on, when threshold studies were undertaken, the period of injection was 1 min. in all cases.

CONTROL OBSERVATIONS

In studies based on subjective impressions adequate control observations are imperative. Therefore (1) we obtained numerous records of the increase in pain with time in the absence of any injection; (2) we sometimes injected distilled water; and (3) in determining threshold doses we injected subliminal quantities of analgesics, the subject being unaware of the nature or the dose of the injected drug. In all these instances there was a steady increase in intensity of pain to a value of 8 units in 8–15 min. Under the conditions of our experiments there were some minor fluctuations in the ischæmic pain, but these were in no way comparable with the clear-cut relief of pain produced by an adequate dose of an analgesic.

Fig. 1 illustrates the absence of effect of an injection of distilled water in a subject (J. W. M.) who was expecting an injection of an effective dose of pethidine and was extremely disappointed with his inability to record any analgesia. The rate of increase in pain intensity after distilled water compared with a typical rate of increase in the absence of a injection; the curves are clearly very similar.

Fig. 2 shows curves obtained from subjects R. M. L. D. an C. A. K. when they received subliminal doses of [illegible] (0·25 mg.) and C.B.11 (0·20 mg.) respectively. In both cas the rate of increase in pain intensity was similar to th recorded when no injection was given.

RESULTS OF INJECTION OF ANALGESICS

Intravenous injection of morphine, pethidine, ph septone, or C.B.11 produced effects which develop either during the latter part of the injection or 1 or min. after the injection. The effects rapidly became max mal with the larger doses—e.g., 5·0–7·5 mg. of morphi or of physeptone, and 50–75 mg. of pethidine— the relief of pain was associated with well-mark side-effects (see below).

A typical illustration of the analgesic action is seen fig. 3, which shows the effect of 5 mg. of physeptone inject in 1 min. in subject J. W. M. The relief of pain was complet but the effect was transient, and subsequently the p increased rapidly. The brief duration of the analgesia was d partly to the fact that the intensity of the ischæmic mus pain was increasing continuously and soon overcame t initial maximal effect of the intravenous analgesic, and part to redistribution of the drug from its original site of fixati in the brain. With smaller doses the relief of pain w proportionately less.

At first we tried to compare the analgesic potenc by finding the smallest dose which would produ complete relief of pain of 4–5 units intensity, as shown, f example, for subject J. W. M. with physeptone (fig. This method of comparison suggested that 7·5 mg. morphine was equivalent to 7·5 mg. of physeptone an to 75·0 mg. of pethidine; in other words, morphine an physeptone were equianalgesic, and both were abo 10 times as potent as pethidine. However, such lar doses produced side-effects which were too great, and aft effects which were too protracted, for the necessary repeated observations. So we finally decided to determine the threshold dose of each drug—i.e., the smallest dose which would produce a definite effect on 4–5 units of pain. Such tests were found most satisfactory and had the great advantage of causing little general disturbance and no after effects, with the result that several tests could be made in a week. Over short periods—e.g., a few weeks—the threshold values remained constant; but, when tests were repeated after several month changes in threshold doses were found (see below).

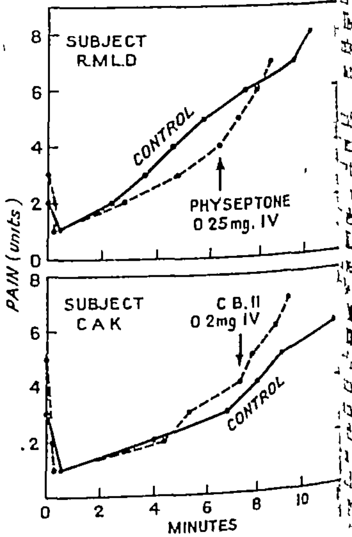

Fig. 2—Effects of injections of subliminal dose of analgesics on ischæmic muscular pain i forearm (55 contractions in subject R. M. L. D. and 50 contractions in subject C A K.) com pared with increase of pain without an injection. Note similarity of curves.

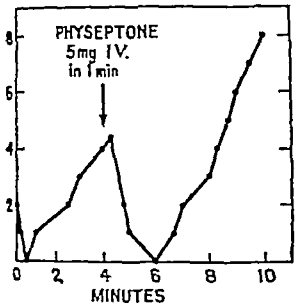
DETERMINATION OF THRESHOLD DOSE

The threshold dose for each drug was determined as follows:

Doses well above and well below the threshold were given. Next the range was narrowed till there was only a small difference between the effective and ineffective doses. During this period of testing, the response to a previously determined threshold dose of another drug was usually retested to check the subject's sensitivity.

For example, with subject C. A. K. 0·2 mg. of C.B.11 had no effect, but 0·3 mg. reduced the pain intensity from 4 to 2 units. The threshold dose was taken as 0·25 mg. In other instances the subject's response was of a border-line character, a sort of plateau effect in which the pain curve was just affected. The dose which produced such a response was accepted as the threshold value.



1—Analgesic action of physeptone on mic muscular pain in forearm contractions) in subject J. W. M

Threshold determinations gave diff- t results in the three persons studied. The threshold s found for several drugs were as follows:

Drug	C. A. K.	J. W. M.	R. M. L. D.
rphine	0·002 mg.	0·1 mg.	0·35 mg.
hidine	7·5 mg.	1 mg.	7·5 mg.
eptone	0·25 mg.	0·1 mg.	0·3 mg.
11	0·25 mg.	0·01 mg.	0·4 mg.
midone	0·3 mg.	—	—
chst 10582 ..	0·4 mg.	—	—

in subject C. A. K. physeptone and C.B.11 were both mes as potent as pethidine (the action of morphine was ptional in this person and is discussed below). In subject M. morphine and physeptone were both 10 times as nt as pethidine, but were only 1/10 as powerful as C.B.11. subject R. M. L. D. morphine, physeptone, and C.B.11 were t equianalgesic and were 20–25 times more potent than dine.

These results may be compared with the figures d by Thorp et al. (1947) in experiments on a in rats, in which morphine and physeptone equally active and about 10 times as potent as dine.

We think that individual variations in sensitivity to esics are important. Subject J. W. M. was always e responsive to analgesic drugs than subject R. M. L. D. difference was seen at all dosage levels but was t clearly shown in the threshold measurements. ject C. A. K. closely resembled subject R. M. L. D. ept in his response to morphine. These differences ld hardly be attributed solely to differences in body- ght (J. W. M. weighed 11 st. 1 lb., R. M. L. D. 13 st., d C. A. K. 13 st. 4 lb.).

It is therefore obvious that clinical differences in ponse to analgesics can, at least in part, be ascribed differences in sensitivity towards them. Since in our eriments the drugs were given intravenously, the erences in sensitivity cannot be due to variable rption and must therefore represent true differences analgesic potency. In patients variable absorption m the gut or from the site of injection will contribute ther possibilities for variation in response.

CHANGES IN THRESHOLD WITH TIME

We have already pointed out that the threshold should determined in a short time. The reason for this ecaution is that the threshold may change after eral months. It would perhaps be generally expected, om the well-known development of tolerance to orphine, that the threshold would rise with the regular rformance of these analgesic tests, but the exact posite was invariably found.

For example, on June 12, 1947, in subject R. M. L. D. e threshold dose of physeptone was 2·5 mg., whereas n Jan. 7, 1948, it was 0·4 mg. Threshold values were not usually determined in the earlier part of our work; hence precise differences in sensitivity cannot be stated, but the responses to supraliminal doses undoubtedly increased with time. Thus in subject J. W. M. the initial response to 1 mg. of C.B.11 was a reduction of pain from 5 to 2 units; this same response later was given to 0·1 mg. of C.B.11.

In general the increase in sensitivity appeared to be about equal for all the drugs studied, and was probably due, at least in part, to the acquisition of greater skill in recognising small changes in pain intensity, but we feel that some true increase in sensitivity must also have developed.

In subject C. A. K. an extraordinary increase in sensitivity to morphine developed. In May and June, 1947, the effect of 5·0 and 7·5 mg. was to reduce the pain from 4 units to 1 unit and from 4 units to 0 respectively. These doses produced a definite subjective feeling of respiratory depression and a characteristic occipital headache. The reaction was rather unpleasant at first but was followed by euphoria. On Oct. 24, 1947, it was intended to repeat the 5 mg. dose to see how far the response had changed. When only 2·5 mg. of morphine had been given in 1/2 min., the effects developed very suddenly and were much greater in all respects than with 7·5 mg. of morphine five months earlier. Subsequently 0·3 mg. produced an effect definitely greater than did the original 7·5 mg. dose, and later the threshold dose was about 0·002 mg.

Such an increase in sensitivity (about a thousandfold) might suggest an allergic response; but, unlike such a reaction, the hypersensitivity concerned all the pharmacological effects originally elicited by the larger doses. Analgesia, respiratory depression, and occipital headache were about equally intensified. The threshold dose of morphine in J. W. M. was 0·1 mg., and in R. M. L. D. 0·35 mg. The cause of this remarkable sensitisation is not clear, but it might be related to the intravenous route of administration.

ANÆSTHETIC GASES

The analgesic actions of nitrous oxide and cyclopropane were easily demonstrated by the ischæmic-pain method.

Nitrous oxide was given in concentrations of 10–40% in oxygen, the proportions being measured with a rotameter. The ischæmic pain was allowed to develop till the intensity had reached 4 or 5 units, when the gas was inhaled.

A typical result, in subject R. M. L. D., is shown in fig. 4, where inhalation of 20% nitrous oxide and 80% oxygen reduced the pain from 4 units to 1 unit and greatly delayed the increase in pain intensity which would normally have been expected.

In subject J. W. M. the following results were obtained:

Nitrous oxide		*Oxygen*		*Result*
10%	..	90%	..	No effect on pain
15%	..	85%	..	Pain fell from 5→3 units
20%	..	80%	..	,, ,, ,, 5→1 unit
30%	..	70%	..	,, ,, ,, 5→1 ,,
40%	..	60%	..	,, ,, ,, 5→0 ,,

Minnitt's apparatus was also tested for its effect on ischæmic muscle pain, 45% nitrous oxide and 55% air

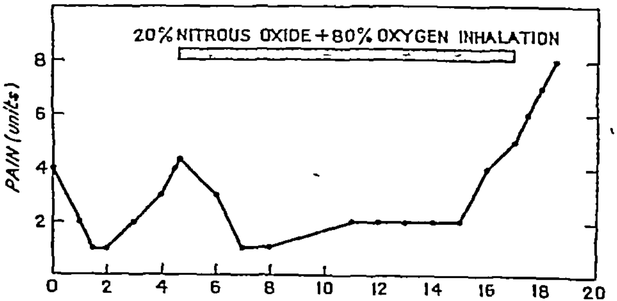


Fig. 4—Analgesic action of nitrous oxide on ischæmic muscular pain in forearm (55 contractions) in subject R. M. L. D.

TESTS OF ANALGESICS

In testing the effects of analgesics the pain was allowed to reach a value of 4–5 units. The drug to be tested was then administered—gases by inhalation, and other drugs by intravenous injection. The gases studied were *nitrous oxide and* cyclopropane. Nitrous oxide was given in concentrations of 10–40% in oxygen, and cyclopropane in concentrations of 2–3% in oxygen. The proportions of the gases in oxygen were measured with a 'Rotameter,' and the rate of flow was kept fast enough to prevent rebreathing.

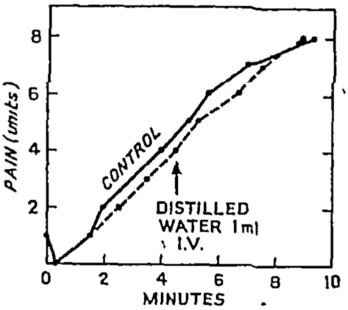

Fig. 1—Effect of injection of distilled water on ischæmic muscular pain in forearm after 55 contractions in subject J. W. M. compared with increase of pain without any injection. Note similarity of curves.

The analgesics given by intravenous injection were as follows:

(1) Morphine (sulphate or hydrochloride).
(2) Pethidine hydrochloride.
(3) *dl*-2-dimethylamino-4 : 4-diphenyl-heptan-5-one hydrochloride (' Physeptone,' ' Amidone,' ' Miadone,' ' Hoechst 10820 ').
(4) *dl*-1-dimethylamino-3 : 3-diphenyl-hexan-4-one hydrochloride (' Hoechst 10582 ').
(5) *dl*-2-dimethylaminomethyl-3 : 3-diphenyl-hexan-4-one hydrochloride (' Isoamidone ').
(6) *dl*-2-l'morpholino-4 : 4-diphenyl-heptan-5-one hydrochloride (' C.B.11 ').
(7) Procaine hydrochloride.
(8) Thiopentone soluble.
(9) ' Benadryl ' hydrochloride.
(10) N-p-methoxybenzyl-N-dimethylaminoethyl-2-aminopyridine maleate (' Neoantergan,' ' Anthisan,' pyranisamine maleate).
(11) N-phenyl-N-benzyl-2-methylimidazoline (' Antistin ').
(12) Tetraethylammonium bromide (T.E.A.B.).

When morphine, pethidine, and physeptone were given in larger doses, the rate of intravenous injection was 5 mg. per min. for morphine and physeptone, and 50 mg. per min. for pethidine. The maximal doses of morphine, physeptone, and pethidine were 7·5 mg., 7·5 mg., and 75·0 mg. respectively. When the duration of injection was varied with the dose, the needle was kept in the vein for the maximal period of 1½ min., so that the subject could not guess the size of the injected dose from the duration of its administration. Later on, when threshold studies were undertaken, the period of injection was 1 min. in all cases.

CONTROL OBSERVATIONS

In studies based on subjective impressions adequate control observations are imperative. Therefore (1) we obtained numerous records of the increase in pain with time in the absence of any injection; (2) we sometimes *injected distilled water; and (3) in determining threshold* doses we injected subliminal quantities of analgesics, the subject being unaware of the nature or the dose of the injected drug. In all these instances there was a steady increase in intensity of pain to a value of 8 units in 8–15 min. Under the conditions of our experiments there were some minor fluctuations in the ischæmic pain, but these were in no way comparable with the clear-cut relief of pain produced by an adequate dose of an analgesic.

Fig. 1 illustrates the absence of effect of an injection of distilled water in a subject (J. W. M.) who was expecting an injection of an effective dose of pethidine and was extremely disappointed with his inability to record any analgesia. The rate of increase in pain intensity after distilled water compared with a typical rate of increase in the absence of a injection; *the curves are clearly very similar.*

Fig. 2 shows curves obtained from subjects R. M. L. D. an C. A. K. when they received subliminal doses of physepto (0·25 mg.) and C.B.11 (0·20 mg.) respectively. In both cas the rate of increase in pain intensity was similar to th recorded when no injection was given.

RESULTS OF INJECTION OF ANALGESICS

Intravenous injection of morphine, pethidine, ph septone, or C.B.11 produced effects which develop either during the latter part of the injection or 1 or min. after the injection. The effects rapidly became ma mal with the larger doses—e.g., 5·0–7·5 mg. of morphi or of physeptone, and 50–75 mg. of pethidine—a the relief of pain was associated with well-mark side-effects (see below).

A typical illustration of the analgesic action is seen fig. 3, which shows the effect of 5 mg. of physeptone inject in 1 min. in subject J. W. M. The relief of pain was complet but the effect was transient, and subsequently the pa increased rapidly. The brief duration of the analgesia was d partly to the fact that the intensity of the ischæmic mus pain was increasing continuously and soon overcame t initial maximal effect of the intravenous analgesic, and par to redistribution of the drug from its original site of fixat in the brain. With smaller doses the relief of pain w proportionately less.

At first we tried to compare the analgesic potenc by finding the smallest dose which would produ complete relief of pain of 4–5 units intensity, as shown, f example, for subject J. W. M. with physeptone (fig. This method of comparison suggested that 7·5 mg. morphine was equivalent to 7·5 mg. of physeptone an *to 75·0 mg. of pethidine; in other words,* morphine a physeptone were equianalgesic, and both were abo 10 times as potent as pethidine. However, such lar doses produced side-effects which were too great, and aft effects which were too protracted, for the necessary repeated observations. So we finally decided to determine the threshold dose of each drug—i.e., the smallest dose which would produce a definite effect on 4–5 units of pain. Such tests were found most satisfactory and had the great advantage of causing little general disturbance and no after effects, with the result that several tests could be made in a week. *Over* short periods—e.g., a few weeks—the threshold values remained constant; but, when tests were repeated after several months, changes in threshold doses were found (see below).

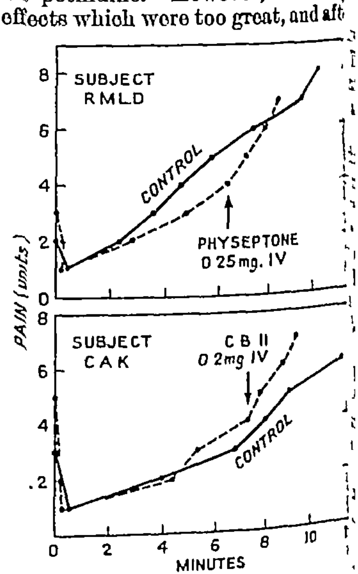

Fig. 2—Effects of injections of subliminal doses of analgesics on ischæmic muscular pain in forearm (55 contractions in subject R. M. L. D. and 50 contractions in subject C. A. K.) compared with increase of pain without any injection. **Note similarity of curves.**

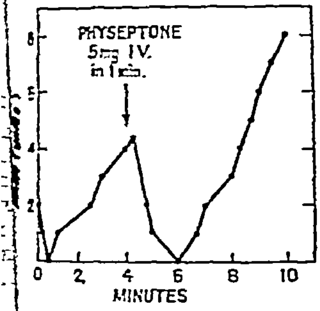
DETERMINATION OF THRESHOLD DOSE

The threshold dose for each drug was determined as follows:

Doses well above and well below the threshold were given. Next the range was narrowed till there was *only* a small difference between the effective and ineffective doses. During period of testing, the response to a previously determined old dose of another drug was usually retested to check subject's sensitivity.

For example, with subject C. A. K. 0·2 mg. of C.B.11 had no effect, but 0·3 mg. reduced the pain intensity from 4 to 2 units. The threshold dose was taken as 0·25 mg. In other instances the subject's response was of a border-line character, a sort of plateau effect in which the pain curve was just affected. The dose which produced such a response was accepted as the threshold value.



1—Analgesic action of physeptone on mic muscular pain in forearm contractions) in subject J. W. M

Threshold determinations gave different results in the three persons studied. The threshold [illegible] found for several drugs were as follows:

Drug	C. A. K.	J. W. M.	R. M. L. D.
phine	0·002 mg.	0·1 mg.	0·35 mg.
dine	7·5 mg.	1 mg.	7·5 mg.
ptone	0·25 mg.	0·1 mg.	0·3 mg.
11	0·25 mg.	0·01 mg.	0·4 mg.
idone	0·3 mg.	—	—
st 10582 ..	0·4 mg.	—	—

in subject C. A. K. physeptone and C.B.11 were both [illegible] times as potent as pethidine (the action of morphine was abnormal in this person and is discussed below). In subject J. W. M. morphine and physeptone were both 10 times as as pethidine, but were only 1/10 as powerful as C.B.11. ject R. M. L. D. morphine, physeptone, and C.B.11 were equianalgesic and were 20–25 times more potent than [illegible].

results may be compared with the figures d by Thorp et al. (1947) in experiments on a in rats, in which morphine and physeptone equally active and about 10 times as potent as ne.

e think that individual variations in sensitivity to esics are important. Subject J. W. M. was always e responsive to analgesic drugs than subject R. M. L. D. difference was seen at all dosage levels but was clearly shown in the threshold measurements. ect C. A. K. closely resembled subject R. M. L. D. t in his response to morphine. These differences d hardly be attributed solely to differences in body-ht (J. W. M. weighed 11 st. 1 lb., R. M. L. D. 13 st., C. A. K. 13 st. 4 lb.).

t is therefore obvious that clinical differences in onse to analgesics can, at least in part, be ascribed fferences in sensitivity towards them. Since in our riments the drugs were given intravenously, the rences in sensitivity cannot be due to variable ption and must therefore represent true differences algesic potency. In patients variable absorption the gut or from the site of injection will contribute er possibilities for variation in response.

CHANGES IN THRESHOLD WITH TIME

We have already pointed out that the threshold should determined in a short time. The reason for this aution is that the threshold may change after ral months. It would perhaps be generally expected, the well-known development of tolerance to phine, that the threshold would rise with the regular formance of these analgesic tests, but the exact osite was invariably found.

For example, on June 12, 1947, in subject R. M. L. D. threshold dose of physeptone was 2·5 mg., whereas Jan. 7, 1948, it was 0·4 mg. Threshold values were not usually determined in the earlier part of our work; hence precise differences in sensitivity cannot be stated, but the responses to supraliminal doses undoubtedly increased with time. Thus in subject J. W. M. the initial response to 1 mg. of C.B.11 was a reduction of pain from 5 to 2 units; this same response later was given to 0·1 mg. of C.B.11.

In general the increase in sensitivity appeared to be about equal for all the drugs studied, and was probably due, at least in part, to the acquisition of greater skill in recognising small changes in pain intensity, but we feel that some true increase in sensitivity must also have developed.

In subject C. A. K. an extraordinary increase in sensitivity to morphine developed. In May and June, 1947, the effect of 5·0 and 7·5 mg. was to reduce the pain from 4 units to 1 unit and from 4 units to 0 respectively. These doses produced a definite subjective feeling of respiratory depression and a characteristic occipital headache. The reaction was rather unpleasant at first but was followed by euphoria. On Oct. 24, 1947, it was intended to repeat the 5 mg. dose to see how far the response had changed. When only 2·5 mg. of morphine had been given in 1/2 min., the effects developed very suddenly *and were much greater in all respects than with 7·5 mg. of* morphine five months earlier. Subsequently 0·3 mg. produced an effect definitely greater than did the original 7·5 mg. dose, and later the threshold dose was about 0·002 mg.

Such an increase in sensitivity (about a thousandfold) might suggest an allergic response; but, unlike such a reaction, the hypersensitivity concerned all the pharmacological effects originally elicited by the larger doses. Analgesia, respiratory depression, and occipital headache were about equally intensified. The threshold dose of morphine in J. W. M. was 0·1 mg., and in R. M. L. D. 0·35 mg. The cause of this remarkable sensitisation is not clear, but it might be related to the intravenous route of administration.

ANÆSTHETIC GASES

The analgesic actions of nitrous oxide and cyclopropane were easily demonstrated by the ischæmic-pain method.

Nitrous oxide was given in concentrations of 10–40% in oxygen, the proportions being measured with a rotameter. The ischæmic pain was allowed to develop till the intensity had reached 4 or 5 units, when the gas was inhaled.

A typical result, in subject R. M. L. D., is shown in fig. 4, where inhalation of 20% nitrous oxide and 80% oxygen reduced the pain from 4 units to 1 unit and greatly delayed the increase in pain intensity which would normally have been expected.

In subject J. W. M. the following results were obtained:

Nitrous oxide	*Oxygen*	*Result*
10% ..	90% ..	No effect on pain
15% ..	85% ..	Pain fell from 5→3 units
20% ..	80% ..	,, ,, ,, 5→1 unit
30% ..	70% ..	,, ,, ,, 5→1 ,,
40% ..	60% ..	,, ,, ,, 5→0 ,,

Minnitt's apparatus was also tested for its effect on ischæmic muscle pain, 45% nitrous oxide and 55% air

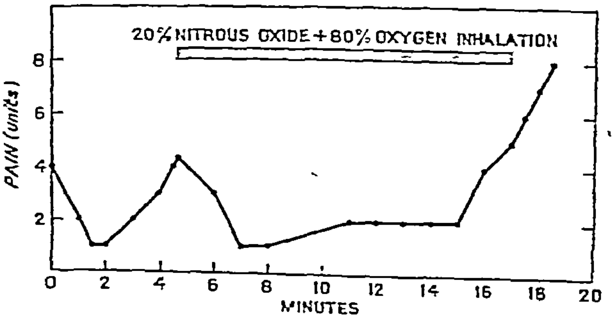


Fig. 4—Analgesic action of nitrous oxide on ischæmic muscular pain in forearm (55 contractions) in subject R. M. L. D.

being inhaled. In subject C. A. K. in three separate experiments the pain was reduced from 5 units to 0, 6 units to 0, and 8 units to 1 unit. In A. J. H. H. pain was reduced from 8 to 4 units.

Cyclopropane was studied in a similar way, 2% and 3% cyclopropane in oxygen being given. The results were as follows :

Cyclopropane	*J. W. M.*	*C. A. K.*	*R. M. L. D.*	*A. J. H. H.*
2% ..	4→2 units	4→1 unit	4→2 units	5→3 units
3% ..	6→1 unit	4→1 ,,	3→1 unit	6→2 ,,

The effects of both these gases were associated with the usual subjective responses noted during induction of anæsthesia with these agents, the degree of such response being proportional to the concentration of anæsthetic gas. In no case did loss of consciousness result, though 40% nitrous oxide almost produced this effect. These results agree very well with those of Seevers et al. (1937), who observed the analgesic actions of such concentrations of these gases on the response to pinpricks of graded pressure.

INTRAVENOUS PROCAINE

The analgesic actions of intravenous procaine have been described by Lundy (1942), Gordon (1943), Allen (1945), and McLachlin (1945). It has been suggested that procaine administered by this route may act either locally on nerve-endings in regions where increased capillary permeability allows greater escape of procaine from the blood-stream, as might happen in burns, or by an action on the central nervous system probably similar to that of well-known analgesics such as morphine and pethidine.

The ischæmic-pain test shows whether the analgesic action of procaine is central or peripheral. If its intravenous administration relieves this pain, the drug must act somewhere central to the site of arterial occlusion in the upper arm, since none of the drug can penetrate to the site of pain production in the ischæmic muscle.

Procaine has been given intravenously to four persons, the dose being 50 mg. in 1 min., or 100 mg. in 2 min. Analgesia of different degrees was produced in all of eight experiments as follows :

Procaine dose	*C. A. K.*	*J. W. M.*	*R. M. L. D.*	*A. J. H. H.*
50 mg. in 1 min.	4→3 units	5→2 units	—	—
100 mg. in 2 min.	4→0 unit	—	6→2 units	4→0 unit
,, ,, ,,	4→1 ,,	—	—	4→0 ,,
,, ,, ,,	4→1 ,,	—	—	—

There is thus no doubt that intravenous procaine can relieve pain by a central action. This does not exclude the possibility of a peripheral action as well, but the latter component is likely to be very small, since extreme dilution of the procaine will have taken place by the time it reaches the affected part. In our experiments procaine analgesia was accompanied by side-effects such as giddiness, light-headedness, nystagmus, and a sensation of respiratory depression.

THIOPENTONE

Thiopentone has also been shown to exert an analgesic effect on ischæmic muscle pain. Thus 100 mg. of sodium thiopentone injected intravenously in 15 sec. produced relief of pain generally comparable to that produced by 30–40% nitrous oxide. The results in four persons were as follows :

J. W. M.	*R. M. L. D.*	*C. A. K.*	*A. J. H. H.*
4→0 unit ..	4→1 unit ..	4→1 unit ..	4→2 units

None of the persons lost consciousness with this dose, but such side-effects as drowsiness, giddiness, a feeling of remoteness, and confusion were well marked, which may have impaired judgment of the results.

ANTI-HISTAMINE DRUGS

It is well known that the anti-histamine drugs have actions unrelated to their antagonism to histamine. For example, they are mostly more powerful local ane thetics than procaine, and they have also been claime to be weak analgesics in rats. We therefore studied tl actions of some of these compounds on ischæmic musc pain. Benadryl, antistin, and neoantergan were giv intravenously, and the following threshold doses we found in the two persons tested :

Drug	*C. A. K.*	*R. M. L. D.*
Benadryl	5·0 mg. ..	5·0 mg.
Antistin	7·5 mg. ..	12·5 mg.
Neoantergan ..	2·0 mg. ..	7·5 mg.

TETRAETHYLAMMONIUM BROMIDE (T.E.A.B.)

The actions of T.E.A.B. have recently been studied connexion with its ganglionic blocking effects, w particular relation to sympathetic control of vaso tone in the limbs. A patient with causalgia, under t care of Prof. A. Kekwick, showed relief of this pain at intravenous injection of 200 mg. of T.E.A.B. This d produced a well-marked fall in blood-pressure.

The possibility of a central analgesic action w investigated by injecting T.E.A.B. intravenously i subjects R. M. L. D. (75 mg.) and C. A. K. (100 mg.), wl ischæmic pain had been produced in the usual way. B persons noted slight relief of pain ; but, when the do of T.E.A.B. are compared with the threshold doses of ot compounds studied, it will be seen that T.E.A.B. is a v feeble analgesic. However, it may well be that the re of causalgic pain recorded by Conley et al. (1947) a injection of up to 500 mg. of T.E.A.B. was due more t central analgesic action than to any circulatory chan

SIDE-EFFECTS OF ANALGESIC DRUGS

When the larger doses of morphine (5·0–7·5 m pethidine (25–75 mg.), physeptone (2·5–7·5 mg.), or C.B (1·0–2·5 mg.) were given, side-effects were well mar and usually so characteristic that the drug could readily identified. Apart from differences between various drugs there were differences between individ responses to the same drug. In studies on threshold do it was found that with slightly supraliminal do analgesia could sometimes be obtained without side-effects.

For example, subject J. W. M. had no side-effects with C 11 in doses less than 0·5 mg., but the threshold analgesic d was 0·01 mg. ; and subject R. M. L. D. had no side-effe with physeptone in doses less than 2·5 mg. (threshold d 0·3 mg.). On the other hand, subject R. M. L. D. showed si effects with morphine in doses down to 0·1 mg., but analgesia with doses less than 0·4 mg.

Thus there was usually analgesia before the onset side-effects, but sometimes the order was reversed. Th might well explain differences in clinical response analgesics.

The most important side-effect with morphine, pet dine, physeptone, and C.B.11 was euphoria, which last for several hours after the larger doses of these dru This feeling of well-being usually outlasted other si effects and in some instances persisted for 24 hours. T four subjects showed differences in their liability euphoria, the order for the four drugs in each subje being as follows :

C. A. K. : (1) physeptone, (2) pethidine, (3) morphi (4) C.B.11.

J. W. M. : (1) pethidine, (2) physeptone, (3) morphi (4) C.B.11.

R. M. L. D. : (1) pethidine, (2) physeptone, (3) morphi (4) C.B.11.

A. J. H. H. : (1) morphine, (2) pethidine, (3) physepto (C.B.11 not tested).

The position of C.B.11 may have been due to the use small doses of this drug. The differences between othe drugs were partly due to accompanying dysphoric effect —e.g., nausea and giddiness, which would easily out weigh any tendency to look on the brighter side of lif importance of euphoria lies in its close relation to liability to drug addiction.

The other drugs had different effects on mood. The effects of nitrous oxide were pleasant but differed from those of the drugs just mentioned. The effects of procaine. especially when given by continuous infusion. were described by subjects A. J. H. H. and C. A. K. as definitely pleasant. There was no euphoria with thiopentone. the antihistamine drugs. or T.E.A.B.

Other side-effects noted with all the drugs included light-headedness, giddiness, and a feeling of remoteness. With pethidine, physeptone. and procaine nystagmus with blurred and double vision was often noted. Morphine, pethidine, physeptone, C.B.11, and procaine are all liable to produce a sensation of difficulty in breathing. Thiopentone produced confusion and well-marked drowsiness in all subjects. Neoantergan produced drowsiness even in threshold doses with subject C. A. K. but not with subject R. M. L. D.

DISCUSSION

The various methods hitherto used to test analgesics in animals and man have all involved measurement of the threshold of a painful stimulus of brief duration. In Macht et al. (1916) used a faradic current; Seevers and Pfeiffer (1936) measured the response to graded pressure with von Frey's hairs or needle prick; Hardy et al. (1940) applied radiant heat to the blackened skin of the forehead; Goetzl et al. (1943) applied an alternating current to a dental filling; and Harrison and [illegible] (1943) measured the number of ischæmic muscle contractions in the forearm required to produce pain.

It is plainly an advantage to be able to measure the strength of stimulus, but it must be remembered that analgesics are most often given to patients in whom pain is already present at a level well above threshold. Hardy et al. (1940) have shown that, when morphine is given to persons enduring experimentally induced pain, the threshold-raising action of the drug is almost completely abolished. They suggest that the relief of pain by morphine is due largely to detachment of pain perception from a psychological reaction pattern involving withdrawal, fear, flight, and anxiety, and to the production of lethargy and sleep. The response to analgesics of patients with severe pain may therefore not be closely related to pain-threshold-raising mechanisms. It should be emphasised that in our work the word "threshold" applies to the dose of drug given and not the strength of stimulus.

The most satisfactory procedure would be to compare the potency of analgesics in patients actually suffering from pain, since in any case this is the final field of application. Intelligent coöperative persons with chronic pain can sometimes, in our experience (which confirms that of Keele 1948), give reliable interpretations of their sensation of pain, and can give assessments of the intensity of pain which correlate well with variations in dosage of a given drug and with changes from one drug to another. But it is not always easy to find subjects with all the necessary qualifications, since chronic pain may arise from diseases which make accurate observation difficult, and the emotional reactions to continuous pain may render coöperation impossible. It was for these reasons that our work was directed to experimentally induced pain in man, and our method of testing may be regarded as intermediate between pain-threshold and clinical studies.

The purely subjective assessment of pain calls for comment. Some patients could describe 4 or 5 grades of intensity of pain quite readily and with apparent consistency. It was thought that what patients of various grades of intelligence and powers of description could do student volunteers and members of the academic staff might do as well, if not better. With experience and practice it was found possible to distinguish about 10 grades of ischæmic muscle pain, the greater fineness of discrimination being perhaps due to the fact that the pain was steadily increasing during a short time (10–15 min.), no feats of memory of previous intensities of pain being required. Moreover, the constant number of ischæmic muscular contractions ensured fairly comparable curves of pain intensity in different experiments.

Hardy et al. (1947) have made observations on a pain-intensity scale, using thermal radiation pain in the skin. They recorded 21 just perceptible steps between threshold sensation and ceiling pain. They have adopted as the unit of pain intensity the dol: 1 dol = 2 just-perceptible steps in discrimination of stimulus intensity. The whole range of pain intensity would thus equal 10½ dols. Our distinction of only 10 grades of intensity of pain (instead of 21 grades) may be related to the differences in character of a deep as opposed to a superficial pain.

The importance of adequate control studies has been fully appreciated in the course of this work, and the injection of distilled water or subthreshold doses of the analgesics gave consistently negative results. It is true that an increase in sensitivity to morphine, pethidine, and physeptone was recorded. but this change only took place over a long time and (apart from the remarkable response of subject C. A. K. to morphine) was similar for these three drugs. When tests were made at short intervals there were no discrepancies.

It might still be suggested that, instead of subjective criteria, however well controlled, objective measurements of accompaniments of pain should be used. The rise of blood-pressure and increase of heart-rate described by Alam and Smirk (1937. 1938) and the diminution in electrical skin resistance (Thompson and Gellhorn 1945). all noted during ischæmic muscular pain, were considered but, after preliminary tests, were found to be of little value. First. the extent of such changes varies widely from person to person; secondly, such changes are very small or non-existent with mild or moderate pain; and thirdly, analgesics might affect these readings by mechanisms distinct from the central relief of pain.

This work has shown that individual variations in sensitivity to both relief of pain and development of side-effects may be considerable. It seems likely that these variations are important in relation to the therapeutic effectiveness of these drugs in the relief of pain in disease.

(1) Variations in sensitivity to analgesic action will mean that with a given dose some persons will get better relief of pain than others.

(2) Side-effects may arise much more readily in some people than in others. Indeed, in some persons side-effects may arise before analgesia is produced. Since, as shown here, the relations between analgesic action and side-effects vary in one person from one drug to another, it is easy to understand why one drug may be therapeutically more satisfactory than another. It is therefore difficult to generalise, and at present it is impossible to explain or to correlate the varied responses seen in different persons.

In patients the relief of pain is more complicated than in these experiments. Our subjects were volunteers interested in the work; it was always known that the duration of pain would be relatively brief—i.e., 15 min. or less—and, more important, that if the subject decided that the pain was intolerable he could instantly procure relief by releasing the cuff. In patients pain is naturally resented, its duration may be considerable, and its appreciation may be linked with anxiety about the disease causing the pain. In these circumstances relief of pain is probably due more to the psychological than to the threshold-raising component of analgesic drug action.

being inhaled. In subject C. A. K. in three separate experiments the pain was reduced from 5 units to 0, 6 units to 0, and 8 units to 1 unit. In A. J. H. H. pain was reduced from 8 to 4 units.

Cyclopropane was studied in a similar way, 2% and 3% cyclopropane in oxygen being given. The results were as follows :

Cyclopropane	*J. W. M.*	*C. A. K.*	*R. M. L. D.*	*A. J. H. H.*
2% ..	4→2 units	4→1 unit	4→2 units	5→3 units
3% ..	6→1 unit	4→1 "	3→1 unit	6→2 "

The effects of both these gases were associated with the usual subjective responses noted during induction of anæsthesia with these agents, the degree of such response being proportional to the concentration of anæsthetic gas. In no case did loss of consciousness result, though 40% nitrous oxide almost produced this effect. These results agree very well with those of Seevers et al. (1937), who observed the analgesic actions of such concentrations of these gases on the response to pinpricks of graded pressure.

INTRAVENOUS PROCAINE

The analgesic actions of intravenous procaine have been described by Lundy (1942), Gordon (1943), Allen (1945), and McLachlin (1945). It has been suggested that procaine administered by this route may act either locally on nerve-endings in regions where increased capillary permeability allows greater escape of procaine from the blood-stream, as might happen in burns, or by an action on the central nervous system probably similar to that of well-known analgesics such as morphine and pethidine.

The ischæmic-pain test shows whether the analgesic action of procaine is central or peripheral. If its intravenous *administration relieves this pain, the drug must* act somewhere central to the site of arterial occlusion in the upper arm, since none of the drug can penetrate to the site of pain production in the ischæmic muscle.

Procaine has been given intravenously to four persons, the dose being 50 mg. in 1 min., or 100 mg. in 2 min. Analgesia of different degrees was produced in all of eight experiments as follows :

Procaine dose	*C. A. K.*	*J. W. M.*	*R. M. L. D.*	*A. J. H. H.*
50 mg. in 1 min.	4→3 units	5→2 units	—	—
100 mg. in 2 min.	4→0 unit	—	6→2 units	4→0 unit
" " "	4→1 "	—	—	4→0 "
" " "	4→1 "	—	—	—

There is thus no doubt that intravenous procaine can relieve pain by a central action. This does not exclude the possibility of a peripheral action as well, but the latter component is likely to be very small, since extreme dilution of the procaine will have taken place by the time it reaches the affected part. In our experiments procaine analgesia was accompanied by side-effects such as *giddiness, light-headedness, nystagmus, and a sensation* of respiratory depression.

THIOPENTONE

Thiopentone has also been shown to exert an analgesic effect on ischæmic muscle pain. Thus 100 mg. of sodium thiopentone injected intravenously in 15 sec. produced relief of pain generally comparable to that produced by 30–40% nitrous oxide. The results in four persons were as follows :

J. W. M.	*R. M. L. D.*	*C. A. K.*	*A. J. H. H.*
4→0 unit ..	4→1 unit ..	4→1 unit ..	4→2 units

None of the persons lost consciousness with this dose, but such side-effects as drowsiness, giddiness, a feeling of remoteness, and confusion were well marked, which may have impaired judgment of the results.

ANTI-HISTAMINE DRUGS

It is well known that the anti-histamine drugs have actions unrelated to their antagonism to histamine. For example, they are mostly more powerful local ana thetics than procaine, and they have also been claime to be weak analgesics in rats. We therefore studied th actions of some of these compounds on ischæmic musc pain. Benadryl, antistin, and neoantergan were give intravenously, and the following threshold doses we found in the two persons tested :

Drug	*C. A. K.*	*R. M. L. D.*
Benadryl ..	.. 5·0 mg.	.. 5·0 mg.
Antistin ..	.. 7·5 mg.	.. 12·5 mg.
Neoantergan	.. 2·0 mg.	.. 7·5 mg.

TETRAETHYLAMMONIUM BROMIDE (T.E.A.B.)

The actions of T.E.A.B. have recently been studied connexion with its ganglionic blocking effects, w particular relation to sympathetic control of vaso tone in the limbs. A patient with causalgia, under t care of Prof. A. Kekwick, showed relief of this pain af intravenous injection of 200 mg. of T.E.A.B. This d produced a well-marked fall in blood-pressure.

The *possibility of a central analgesic action* w *investigated by injecting* T.E.A.B. *intravenously* i subjects R. M. L. D. (75 mg.) and C. A. K. (100 mg.), wh ischæmic pain had been produced in the usual way. B persons noted slight relief of pain ; but, when the do of T.E.A.B. are compared with the threshold doses of ot compounds studied, it will be seen that T.E.A.B. is a v feeble analgesic. However, it may well be that the re of causalgic pain recorded by Conley et al. (1947) af injection of up to 500 mg. of T.E.A.B. was due more t central analgesic action than to any circulatory chan

SIDE-EFFECTS OF ANALGESIC DRUGS

When the larger doses of morphine (5·0–7·5 m *pethidine (25–75 mg.), physeptone (2·5–7·5 mg.),* or C.B (1·0–2·5 mg.) were given, side-effects were well mar *and usually so characteristic that the drug could* readily identified. Apart from differences between various drugs there were differences between individ responses to the same drug. In studies on threshold do it was found that with slightly supraliminal do analgesia could sometimes be obtained without side-effects.

For example, subject J. W. M. had no side-effects with C 11 in doses less than 0·5 mg., but the threshold analgesic d was 0·01 mg. ; and subject R. M. L. D. had no side-effe with physeptone in doses less than 2·5 mg. (threshold d 0·3 mg.). On the other hand, subject R. M. L. D. showed si effects with morphine in doses down to 0·1 mg., but analgesia with doses less than 0·4 mg.

Thus there was usually analgesia before the onset side-effects, but sometimes the order was reversed. T might well explain differences in clinical response analgesics.

The most important side-effect with morphine, pet dine, physeptone, and C.B.11 was euphoria, which last for several hours after the larger doses of these dru This feeling of well-being usually outlasted other si effects and in some instances persisted for 24 hours. T four subjects showed differences in their liability euphoria, the order for the four drugs in each subj being as follows :

C. A. K. : (1) physeptone, (2) pethidine, (3) morphi (4) C.B.11.

J. W. M. : (1) pethidine, (2) physeptone, (3) morphi (4) C.B.11.

R. M. L. D. : (1) pethidine, (2) physeptone, (3) morphi (4) C.B.11.

A. J. H. H. : (1) morphine, (2) pethidine, (3) physepto (C.B.11 not tested).

The position of C.B.11 may have been due to the use small doses of this drug. The differences between oth drugs were partly due to accompanying dysphoric effec —e.g., nausea and giddiness, which would easily ou weigh any tendency to look on the brighter side of lif importance of euphoria lies in its close relation to ability to drug addiction.

The other drugs had different effects on mood. The es of nitrous oxide were pleasant but differed from of the drugs just mentioned. The effects of procaine. ially when given by continuous infusion. were ibed by subjects A. J. H. H. and C. A. K. as definitely asant. There was no euphoria with thiopentone. the histamine drugs. or T.E.A.B.

her side-effects noted with all the drugs included headedness, giddiness, and a feeling of remoteness. pethidine, physeptone. and procaine nystagmus blurred and double vision was often noted. hine. pethidine, physeptone, C.B.11. and procaine all liable to produce a sensation of difficulty in ing. Thiopentone produced confusion and well-ed drowsiness in all subjects. Neoantergan produced siness even in threshold doses with subject C. A. K. ot with subject R. M. L. D.

With experience and practice it was found possible to distinguish about 10 grades of ischæmic muscle pain, the greater fineness of discrimination being perhaps due to the fact that the pain was steadily increasing during a short time (10–15 min.), no feats of memory of previous intensities of pain being required. Moreover, the constant number of ischæmic muscular contractions ensured fairly comparable curves of pain intensity in different experiments.

Hardy et al. (1947) have made observations on a pain-intensity scale. using thermal radiation pain in the skin. They recorded 21 just perceptible steps between threshold sensation and ceiling pain. They have adopted as the unit of pain intensity the dol: 1 dol = 2 just-perceptible steps in discrimination of stimulus intensity. The whole range of pain intensity would thus equal 10½ dols. Our distinction of only 10 grades of intensity of pain (instead of 21 grades) may be related to the differences in character of a deep as opposed to a superficial pain.

The importance of adequate control studies has been fully appreciated in the course of this work, and the injection of distilled water or subthreshold doses of the analgesics gave consistently negative results. It is true that an increase in sensitivity to morphine, pethidine, and physeptone was recorded, but this change only took place over a long time and (apart from the remarkable response of subject C. A. K. to morphine) was similar for these three drugs. When tests were made at short intervals there were no discrepancies.

It might still be suggested that, instead of subjective criteria, however well controlled. objective measurements of accompaniments of pain should be used. The rise of blood-pressure and increase of heart-rate described by Alam and Smirk (1937. 1938) and the diminution in electrical skin resistance (Thompson and Gellhorn 1945), all noted during ischæmic muscular pain, were considered but. after preliminary tests. were found to be of little value. First. the extent of such changes varies widely from person to person; secondly, such changes are very small or non-existent with mild or moderate pain; and thirdly, analgesics might affect these readings by mechanisms distinct from the central relief of pain.

This work has shown that individual variations in sensitivity to both relief of pain and development of side-effects may be considerable. It seems likely that these variations are important in relation to the therapeutic effectiveness of these drugs in the relief of pain in disease.

(1) Variations in sensitivity to analgesic action will mean that with a given dose some persons will get better relief of pain than others.

(2) Side-effects may arise much more readily in some people than in others. Indeed. in some persons side-effects may arise before analgesia is produced. Since, as shown here, the relations between analgesic action and side-effects vary in one person from one drug to another. it is easy to understand why one drug may be therapeutically more satisfactory than another. It is therefore difficult to generalise, and at present it is impossible to explain or to correlate the varied responses seen in different persons.

In patients the relief of pain is more complicated than in these experiments. Our subjects were volunteers interested in the work; it was always known that the duration of pain would be relatively brief—i.e., 15 min. or less—and. more important, that if the subject decided that the pain was intolerable he could instantly procure relief by releasing the cuff. In patients pain is naturally resented. its duration may be considerable, and its appreciation may be linked with anxiety about the disease causing the pain. In these circumstances relief of pain is probably due more to the psychological than to the threshold-raising component of analgesic drug action.

being inhaled. In subject C. A. K. in three separate experiments the pain was reduced from 5 units to 0, 6 units to 0, and 8 units to 1 unit. In A. J. H. H. pain was reduced from 8 to 4 units.

Cyclopropane was studied in a similar way, 2% and 3% cyclopropane in oxygen being given. The results were as follows:

Cyclopropane	*J. W. M.*	*C. A. K.*	*R. M. L. D.*	*A. J. H. H.*
2% ..	4→2 units	4→1 unit	4→2 units	5→3 units
3% ..	6→1 unit	4→1 ,,	3→1 unit	6→2 ,,

The effects of both these gases were associated with the usual subjective responses noted during induction of anæsthesia with these agents, the degree of such response being proportional to the concentration of anæsthetic gas. In no case did loss of consciousness result, though 40% nitrous oxide almost produced this effect. These results agree very well with those of Seevers et al. (1937), who observed the analgesic actions of such concentrations of these gases on the response to pinpricks of graded pressure.

INTRAVENOUS PROCAINE

The analgesic actions of intravenous procaine have been described by Lundy (1942), Gordon (1943), Allen (1945), and McLachlin (1945). It has been suggested that procaine administered by this route may act either locally on nerve-endings in regions where increased capillary permeability allows greater escape of procaine from the blood-stream, as might happen in burns, or by an action on the central nervous system probably similar to that of well-known analgesics such as morphine and pethidine.

The ischæmic-pain test shows whether the analgesic action of procaine is central or peripheral. If its intravenous administration relieves this pain, the drug must act somewhere central to the site of arterial occlusion in the upper arm, since none of the drug can penetrate to the site of pain production in the ischæmic muscle.

Procaine has been given intravenously to four persons, the dose being 50 mg. in 1 min., or 100 mg. in 2 min. Analgesia of different degrees was produced in all of eight experiments as follows:

Procaine dose	*C. A. K.*	*J. W. M.*	*R. M. L. D.*	*A. J. H. H.*
50 mg. in 1 min.	4→3 units	5→2 units	—	—
100 mg. in 2 min.	4→0 unit	—	6→2 units	4→0 unit
,, ,, ,,	4→1 ,,	—	—	4→0 ,,
,, ,, ,,	4→1 ,,	—	—	—

There is thus no doubt that intravenous procaine can relieve pain by a central action. This does not exclude the possibility of a peripheral action as well, but the latter component is likely to be very small, since extreme dilution of the procaine will have taken place by the time it reaches the affected part. In our experiments procaine analgesia was accompanied by side-effects such as giddiness, light-headedness, nystagmus, and a sensation of respiratory depression.

THIOPENTONE

Thiopentone has also been shown to exert an analgesic effect on ischæmic muscle pain. Thus 100 mg. of sodium thiopentone injected intravenously in 15 sec. produced relief of pain generally comparable to that produced by 30–40% nitrous oxide. The results in four persons were as follows:

J. W. M.	*R. M. L. D.*	*C. A. K.*	*A. J. H. H.*
4→0 unit ..	4→1 unit ..	4→1 unit ..	4→2 units

None of the persons lost consciousness with this dose, but such side-effects as drowsiness, giddiness, a feeling of remoteness, and confusion were well marked, which may have impaired judgment of the results.

ANTI-HISTAMINE DRUGS

It is well known that the anti-histamine drugs have actions unrelated to their antagonism to histamine. For example, they are mostly more powerful local anæ thetics than procaine, and they have also been claime to be weak analgesics in rats. We therefore studied th actions of some of these compounds on ischæmic musc pain. Benadryl, antistin, and neoantergan were giv intravenously, and the following threshold doses we found in the two persons tested:

Drug	*C. A. K.*	*R. M. L. D.*
Benadryl ..	.. 5·0 mg.	.. 5·0 mg.
Antistin ..	.. 7·5 mg.	.. 12·5 mg.
Neoantergan	.. 2·0 mg.	.. 7·5 mg.

TETRAETHYLAMMONIUM BROMIDE (T.E.A.B.)

The actions of T.E.A.B. have recently been studied connexion with its ganglionic blocking effects, w particular relation to sympathetic control of vasc tone in the limbs. A patient with causalgia, under care of Prof. A. Kekwick, showed relief of this pain af intravenous injection of 200 mg. of T.E.A.B. This d produced a well-marked fall in blood-pressure.

The possibility of a central analgesic action *investigated by injecting T.E.A.B. intravenously i* subjects R. M. L. D. (75 mg.) and C. A. K. (100 mg.), wh ischæmic pain had been produced in the usual way. B persons noted slight relief of pain; but, when the do of T.E.A.B. are compared with the threshold doses of ot compounds studied, it will be seen that T.E.A.B. is a v feeble analgesic. However, it may well be that the re of causalgic pain recorded by Conley et al. (1947) a injection of up to 500 mg. of T.E.A.B. was due more t *central analgesic action than to any circulatory chan*

SIDE-EFFECTS OF ANALGESIC DRUGS

When the larger doses of morphine (5·0–7·5 m pethidine (25–75 mg.), physeptone (2·5–7·5 mg.), or C.B (1·0–2·5 mg.) were given, side-effects were well mar and usually so characteristic that the drug could readily identified. Apart from differences between various drugs there were differences between individ responses to the same drug. In studies on threshold do it was found that with slightly supraliminal do analgesia could sometimes be obtained without side-effects.

For example, subject J. W. M. had no side-effects with C 11 in doses less than 0·5 mg., but the threshold analgesic d was 0·01 mg.; and subject R. M. L. D. had no side-effe with physeptone in doses less than 2·5 mg. (threshold d 0·3 mg.). On the other hand, subject R. M. L. D. showed si effects with morphine in doses down to 0·1 mg., but analgesia with doses less than 0·4 mg.

Thus there was usually analgesia before the onset side-effects, but sometimes the order was reversed. T might well explain differences in clinical response analgesics.

The most important side-effect with morphine, pet dine, physeptone, and C.B.11 was *euphoria*, which last for several hours after the larger doses of these dru This feeling of well-being usually outlasted other si effects and in some instances persisted for 24 hours. T four subjects showed differences in their liability euphoria, the order for the four drugs in each subj being as follows:

C. A. K.: (1) physeptone, (2) pethidine, (3) morphi (4) C.B.11.

J. W. M.: (1) pethidine, (2) physeptone, (3) morphi (4) C.B.11.

R. M. L. D.: (1) pethidine, (2) physeptone, (3) morphi (4) C.B.11.

A. J. H. H.: (1) morphine, (2) pethidine, (3) physepton (C.B.11 not tested).

The position of C.B.11 may have been due to the use small doses of this drug. The differences between ot drugs were partly due to accompanying dysphoric effe —e.g., nausea and giddiness, which would easily out weigh any tendency to look on the brighter side of li importance of euphoria lies in its close relation to liability to drug addiction.

The other drugs had different effects on mood. The ons of nitrous oxide were pleasant but differed from e of the drugs just mentioned. The effects of procaine, ecially when given by continuous infusion, were ribed by subjects A. J. H. H. and C. A. K. as definitely pleasant. There was no euphoria with thiopentone, the i histamine drugs, or T.E.A.B.

Other side-effects noted with all the drugs included headedness, giddiness, and a feeling of remoteness. th pethidine, physeptone, and procaine nystagmus blurred and double vision was often noted. phine, pethidine, physeptone, C.B.11, and procaine all liable to produce a sensation of difficulty in thing. Thiopentone produced confusion and well-ked drowsiness in all subjects. Neoantergan produced siness even in threshold doses with subject C. A. K. not with subject R. M. L. D.

DISCUSSION

The various methods hitherto used to test analgesics animals and man have all involved measurement of threshold of a painful stimulus of brief duration. In Macht et al. (1916) used a faradic current; Seevers Pfeiffer (1936) measured the response to graded sure with von Frey's hairs or needle prick; Hardy l. (1940) applied radiant heat to the blackened skin he forehead; Goetzl et al. (1943) applied an alter- ng current to a dental filling; and Harrison and low (1943) measured the number of ischæmic cle contractions in the forearm required to produce .

It is plainly an advantage to be able to measure the gth of stimulus, but it must be remembered that esics are most often given to patients in whom pain dy present at a level well above threshold. Hardy (1940) have shown that, when morphine is given ons enduring experimentally induced pain, the reshold-raising action of the drug is almost tely abolished. They suggest that the relief of by morphine is due largely to detachment of pain ption from a psychological reaction pattern involv- withdrawal, fear, flight, and anxiety, and to the tion of lethargy and sleep. The response to anal- s of patients with severe pain may therefore not be y closely related to pain-threshold-raising mechanisms. hould be emphasised that in our work the word reshold" applies to the dose of drug given and not strength of stimulus.

The most satisfactory procedure would be to compare potency of analgesics in patients actually suffering pain, since in any case this is the final field of appli- n. Intelligent coöperative persons with chronic can sometimes, in our experience (which confirms of Keele 1948), give reliable interpretations of their ation of pain, and can give assessments of the ity of pain which correlate well with variations in ge of a given drug and with changes from one drug another. But it is not always easy to find subjects all the necessary qualifications, since chronic pain arise from diseases which make accurate observa- s difficult, and the emotional reactions to continuous n may render coöperation impossible. It was for these ons that our work was directed to experimentally uced pain in man, and our method of testing may be rded as intermediate between pain-threshold and ical studies.

The purely subjective assessment of pain calls for ment. Some patients could describe 4 or 5 grades of nsity of pain quite readily and with apparent con- ncy. It was thought that what patients of various des of intelligence and powers of description could student volunteers and members of the academic staff might do as well, if not better. With experience and practice it was found possible to distinguish about 10 grades of ischæmic muscle pain, the greater fineness of discrimination being perhaps due to the fact that the pain was steadily increasing during a short time (10–15 min.), no feats of memory of previous intensities of pain being required. Moreover, the constant number of ischæmic muscular contractions ensured fairly comparable curves of pain intensity in different experiments.

Hardy et al. (1947) have made observations on a pain-intensity scale, using thermal radiation pain in the skin. They recorded 21 just perceptible steps between threshold sensation and ceiling pain. They have adopted as the unit of pain intensity the dol: 1 dol = 2 just-perceptible steps in discrimination of stimulus intensity. The whole range of pain intensity would thus equal 10½ dols. Our distinction of only 10 grades of intensity of pain (instead of 21 grades) may be related to the differences in character of a deep as opposed to a superficial pain.

The importance of adequate control studies has been fully appreciated in the course of this work, and the injection of distilled water or subthreshold doses of the analgesics gave consistently negative results. It is true that an increase in sensitivity to morphine, pethidine, and physeptone was recorded, but this change only took place over a long time and (apart from the remarkable response of subject C. A. K. to morphine) was similar for these three drugs. When tests were made at short intervals there were no discrepancies.

It might still be suggested that, instead of subjective criteria, however well controlled, objective measurements of accompaniments of pain should be used. The rise of blood-pressure and increase of heart-rate described by Alam and Smirk (1937, 1938) and the diminution in electrical skin resistance (Thompson and Gellhorn 1945), all noted during ischæmic muscular pain, were considered but, after preliminary tests, were found to be of little value. First, the extent of such changes varies widely from person to person; secondly, such changes are very small or non-existent with mild or moderate pain; and thirdly, analgesics might affect these readings by mechanisms distinct from the central relief of pain.

This work has shown that individual variations in sensitivity to both relief of pain and development of side-effects may be considerable. It seems likely that these variations are important in relation to the therapeutic effectiveness of these drugs in the relief of pain in disease.

(1) Variations in sensitivity to analgesic action will mean that with a given dose some persons will get better relief of pain than others.

(2) Side-effects may arise much more readily in some people than in others. Indeed, in some persons side-effects may arise before analgesia is produced. Since, as shown here, the relations between analgesic action and side-effects vary in one person from one drug to another, it is easy to understand why one drug may be therapeutically more satisfactory than another. It is therefore difficult to generalise, and at present it is impossible to explain or to correlate the varied responses seen in different persons.

In patients the relief of pain is more complicated than in these experiments. Our subjects were volunteers interested in the work; it was always known that the duration of pain would be relatively brief—i.e., 15 min. or less—and, more important, that if the subject decided that the pain was intolerable he could instantly procure relief by releasing the cuff. In patients pain is naturally resented, its duration may be considerable, and its appreciation may be linked with anxiety about the disease causing the pain. In these circumstances relief of pain is probably due more to the psychological than to the threshold-raising component of analgesic drug action.

being inhaled. In subject C. A. K. in three separate experiments the pain was reduced from 5 units to 0, 6 units to 0, and 8 units to 1 unit. In A. J. H. H. pain was reduced from 8 to 4 units.

Cyclopropane was studied in a similar way, 2% and 3% cyclopropane in oxygen being given. The results were as follows :

Cyclopropane	*J. W. M.*	*C. A. K.*	*R. M. L. D.*	*A. J. H. H.*
2% ..	4→2 units	4→1 unit	4→2 units	5→3 units
3% ..	6→1 unit	4→1 ,,	3→1 unit	6→2 ,,

The effects of both these gases were associated with the usual subjective responses noted during induction of anæsthesia with these agents, the degree of such response being proportional to the concentration of anæsthetic gas. In no case did loss of consciousness result, though 40% nitrous oxide almost produced this effect. These results agree very well with those of Seevers et al. (1937), who observed the analgesic actions of such concentrations of these gases on the response to pinpricks of graded pressure.

INTRAVENOUS PROCAINE

The analgesic actions of intravenous procaine have been described by Lundy (1942), Gordon (1943), Allen (1945), and McLachlin (1945). It has been suggested that procaine administered by this route may act either locally on nerve-endings in regions where increased capillary permeability allows greater escape of procaine from the blood-stream, as might happen in burns, or by an action on the central nervous system probably similar to that of well-known analgesics such as morphine and pethidine.

The ischæmic-pain test shows whether the analgesic action of procaine is central or peripheral. If its intravenous administration relieves this pain, the drug must act somewhere central to the site of arterial occlusion in the upper arm, since none of the drug can penetrate to the site of pain production in the ischæmic muscle.

Procaine has been given intravenously to four persons, the dose being 50 mg. in 1 min., or 100 mg. in 2 min. Analgesia of different degrees was produced in all of eight experiments as follows :

Procaine dose	*C. A. K.*	*J. W. M.*	*R. M. L. D.*	*A. J. H. H.*
50 mg. in 1 min.	4→3 units	5→2 units	—	—
100 mg. in 2 min.	4→0 unit	—	6→2 units	4→0 unit
,, ,, ,,	4→1 ,,	—	—	4→0 ,,
,, ,, ,,	4→1 ,,	—	—	—

There is thus no doubt that intravenous procaine can relieve pain by a central action. This does not exclude the possibility of a peripheral action as well, but the latter component is likely to be very small, since extreme dilution of the procaine will have taken place by the time it reaches the affected part. In our experiments procaine analgesia was accompanied by side-effects such as giddiness, light-headedness, nystagmus, and a sensation of respiratory depression.

THIOPENTONE

Thiopentone has also been shown to exert an analgesic effect on ischæmic muscle pain. Thus 100 mg. of sodium *thiopentone injected intravenously in 15 sec. produced* relief of pain generally comparable to that produced by 30–40% nitrous oxide. The results in four persons were as follows :

J. W. M.	*R. M. L. D.*	*C. A. K.*	*A. J. H. H.*
4→0 unit ..	4→1 unit ..	4→1 unit ..	4→2 units

None of the persons lost consciousness with this dose, but such side-effects as drowsiness, giddiness, a feeling of remoteness, and confusion were well marked, which may have impaired judgment of the results.

ANTI-HISTAMINE DRUGS

It is well known that the anti-histamine drugs have actions unrelated to their antagonism to histamine. For example, they are mostly more powerful local ana thetics than procaine, and they have also been claim to be weak analgesics in rats. We therefore studied th actions of some of these compounds on ischæmic musc pain. Benadryl, antistin, and neoantergan were giv intravenously, and the following threshold doses we found in the two persons tested :

Drug	*C. A. K.*	*R. M. L. D.*
Benadryl ..	.. 5·0 mg. ..	5 0 mg.
Antistin ..	.. 7·5 mg. ..	12·5 mg.
Neoantergan	.. 2·0 mg. ..	7·5 mg.

TETRAETHYLAMMONIUM BROMIDE (T.E.A.B.)

The actions of T.E.A.B. have recently been studied connexion with its ganglionic blocking effects, w particular relation to sympathetic control of vaso tone in the limbs. A patient with causalgia, under t care of Prof. A. Kekwick, showed relief of this pain af intravenous injection of 200 mg. of T.E.A.B. This d produced a well-marked fall in blood-pressure.

The possibility of a central analgesic action w investigated by injecting T.E.A.B. intravenously i subjects R. M. L. D. (75 mg.) and C. A. K. (100 mg.), wh ischæmic pain had been produced in the usual way. B persons noted slight relief of pain ; but, when the do of T.E.A.B. are compared with the threshold doses of ot compounds studied, it will be seen that T.E.A.B. is a v feeble analgesic. However, it may well be that the re of causalgic pain recorded by Conley et al. (1947) af injection of up to 500 mg. of T.E.A.B. was due more t *central analgesic action than to any circulatory chan*

SIDE-EFFECTS OF ANALGESIC DRUGS

When the larger doses of morphine (5·0–7·5 m pethidine (25–75 mg.), physeptone (2·5–7·5 mg.), or C.B. (1·0–2·5 mg.) were given, side-effects were well mar and usually so characteristic that the drug could readily identified. Apart from differences between various drugs there were differences between individ responses to the same drug. In studies on threshold do it was found that with slightly supraliminal do analgesia could sometimes be obtained witho side-effects.

For example, subject J. W. M. had no side-effects with d 11 in doses less than 0·5 mg., but the threshold analgesic d was 0·01 mg. ; and subject R. M. L. D. had no side-effe with physeptone in doses less than 2·5 mg. (threshold d 0·3 mg.). On the other hand, subject R. M. L D. showed si effects with morphine in doses down to 0·1 mg., but analgesia with doses less than 0·4 mg.

Thus there was usually analgesia before the onset side-effects, but sometimes the order was reversed. Th might well explain differences in clinical response analgesics.

The most important side-effect with morphine, pet dine, physeptone, and C.B.11 was euphoria, which last for several hours after the larger doses of these dru This feeling of well-being usually outlasted other si effects and in some instances persisted for 24 hours. T four subjects showed differences in their liability euphoria, the order for the four drugs in each subj being as follows :

C. A. K. : (1) physeptone, (2) pethidine, (3) morphi (4) C.B.11.

J. W. M. : (1) pethidine, (2) physeptone, (3) morphi (4) C.B.11.

R. M. L. D. : (1) pethidine, (2) physeptone, (3) morphi (4) C.B.11.

A. J. H. H. : (1) morphine, (2) pethidine, (3) physepto (C.B.11 not tested).

The position of C.B.11 may have been due to the use o small doses of this drug. The differences between oth drugs were partly due to accompanying dysphoric effe —e.g., nausea and giddiness, which would easily ou weigh any tendency to look on the brighter side of li

The complicated cases in the treated group had a rather longer average duration of fever than those in the control group.

CONCLUSION

Our failure to reduce the incidence of chest complications may be explained in one of two ways. First, bacterial infection may have nothing to do with the production of the sticky phlegm which often blocks the air-tubes after operation. Or, secondly, and perhaps more likely, the influence of infection may be important, but a penicillin-resistant flora may be no more desirable—indeed may be more dangerous—than the natural one.

We wish to thank Prof. Ian Aird, Mr. M. R. Ewing, and Prof. Lord Stamp for supervising this inquiry, and Mr. J. W. [illegible] for his help with the statistics. Oxycillin atomisers were lent by Messrs. Oxygenaire Ltd.

TUBERCULOUS MASTOIDITIS TREATED WITH STREPTOMYCIN

REPORT OF A CASE

O. D. FISHER
M.B. Lond., D.C.H.
PÆDIATRIC REGISTRAR

E. A. MALKIN
M.R.C.S., B.Sc. Lond., D.L.O.
LATE HOUSE-SURGEON, EAR, NOSE, AND THROAT DEPARTMENT

KING'S COLLEGE HOSPITAL, LONDON

TUBERCULOUS infection of the middle-ear cleft is a rare condition, especially in infants; it is often complicated by facial palsy and may be followed by destruction of the labyrinth and by meningitis. The following case was treated by surgery and subsequently with streptomycin.

On Dec. 19, 1947, a female infant, aged 8 weeks, was first seen with seven days' history of right otorrhœa and two days' partial right facial paralysis. There was a profuse and foul-smelling discharge from the right ear; the drum-head was not clearly seen, but there appeared to be a granulation which bled freely when touched with a probe. There was slight postauricular œdema. A well-developed right facial palsy was present, incomplete in the distribution of the lower division of the nerve. A submandibular gland on the right side was enlarged, but no preauricular or postauricular glands were palpable. There were no other abnormal physical signs, except that the spleen was just palpable.

On Dec. 21 the clinical appearance strongly suggested a tuberculous infection, and a cortical mastoidectomy was performed under basal paraldehyde and local infiltration with procaine. The skin and periosteum were œdematous; when the cortex was opened a large cavity full of foul-smelling necrotic material was found. After curetting, the lateral sinus plate, horizontal semicircular canal, and incus were clearly seen. The wound was closed, and a small inferior rubber drain was left in situ for thirty-six hours. Penicillin was given systemically, 25,000 units eight-hourly, until Dec. 23.

Streptomycin therapy was begun on Feb. 6, 1948, and continued for thirteen weeks. The dosage was calculated on the basis of 0·02 g. per lb. body-weight daily and given twelve-hourly by intramuscular injection together with 1 ml. of 2·5% procaine (Feldman et al. 1947, Cathie 1948, Medical Research Council 1948). The total dosage was [illegible]5 g. There was no evidence of toxic symptoms referable to the streptomycin at any time.

During the postoperative period the local treatment consisted of mopping out the meatus, but during February and March the meatus was syringed twice daily with hypertonic saline and eusol. The postauricular incision broke down, and a discharge persisted until the middle of March, when it healed for about three weeks. It then discharged again until the end of April, since when the wound has been soundly healed, but the scar is depressed.

The meatal discharge remained offensive and profuse until the third week in March, when it became gradually less, and it dried up completely a month later.

An improvement in the facial paralysis was first noted about the middle of January, and by the second week in March recovery was complete.

Histology.—Prof. H. A. Magnus reported on Dec. 22, 1947, that sections of material from the antrum showed granulation tissue and some areas of caseous necrosis, but no tubercle follicles, and that sections stained by the Ziehl-Neelsen method showed several groups of undoubted tubercle bacilli, the histological appearances of this material being those of a purely exudative lesion.

Bacteriology.—Culture of acid-fast bacilli found in the specimen of pus from the antrim on Dec. 22, 1947, yielded a human str. in of *Myco. tuberculosis.*

Tuberculin Skin tests.—Tuberculin-jelly test negative on Dec. 29, 1947; Mantoux test 1/100,000 negative on Jan. 5, 1948, and 1/10,000 negative on Jan. 8; tuberculin-jelly test positive on Jan. 10.

Blood.—On Jan. 2 a blood-count showed 2,960,000 red cells per c.mm., Hb 58%. The erythrocyte-sedimentation rate (E.S.R.) was 27 mm. in the first hour (Payne). Two transfusions of 50 ml. of group-O Rh-negative blood were given via the internal jugular vein at this time.

Blood-streptomycin Levels.—On Feb. 10, the blood level eight hours after injection was 4 units per ml.; ten hours after injection, 2 units per ml.; and twelve hours after injection, less than 0·25 unit per ml.

Cerebrospinal Fluid (C.S.F.).—Cells 4 per c.mm., protein 30 mg. and chlorides 760 mg. per 100 ml., culture sterile.

Radiograms of chest on Dec. 19, 1947, and May 18, 1948, were clear.

Urine.—No abnormality was found at any time.

Subsequent weekly blood, urine, and C.S.F. examinations were made until the patient's discharge from hospital, when the E.S.R. was 14 mm. in the first hour, Hb 62%. The C.S.F. findings remained constant throughout.

From the past history no source of infection could be ascertained; the child had been born in hospital and subsequently nursed at home. No mouth-to-mouth artificial respiration had been used, and initial feeding was by the breast, later supplemented with a half-cream dried milk. All chest radiograms of immediate contacts were clear.

DISCUSSION

The case is interesting in that streptomycin was used after a cortical mastoidectomy, with apparent resolution in fourteen weeks. Souper (1933) recorded 36 cases of tuberculous mastoiditis in which 17 of the patients were aged under 6 months, and 29 under 12 months, with a mortality of 59% among the first 24 cases treated by radical mastoidectomy. The remainder, treated by a Wilde's incision, a cortical mastoidectomy, or a radical mastoidectomy without a plastic meatal procedure, had a mortality of 36%. This latter and more conservative approach was also advocated by Ormerod (1939), who pointed out that, in acute cases of mastoiditis diagnosed preoperatively as tuberculous, it is usually wise to perform a cortical mastoidectomy and to await healing, which generally takes place after several weeks' dressing. It is also advised that the postauricular wound should be left open and packed with gauze through the meatus and the wound. The radical operation can then be performed if the discharge persists. There also seems to be a place for Wilde's incision in severely ill children with a subperiosteal abscess, to precede the opening of the mastoid.

It remains to be seen whether streptomycin therapy will altogether obviate the need for radical exenteration in these cases and will reduce the high mortality of this condition.

Our thanks are due to Dr. Wilfrid Sheldon and Mr. W. I. Daggett for permission to publish this case, and to Dr. I. A. B. Cathie for the supply of streptomycin, advice regarding dosage, and estimations of blood-streptomycin levels.

SUMMARY

A method of testing analgesics in man has been studied in four normal persons. Maintained ischæmic muscular pain has been produced in the forearm and assessed subjectively in grades of intensity of 1–10 units (1 = very slight, 10 = intolerable pain).

The drugs tested were injected intravenously when moderate pain (4–5 units) was present. Effective doses produced rapid transient relief.

The best method of comparing the potency of different analgesics was to find the smallest dose of each drug which reduced pain of 4–5 units' intensity. The comparative effects of morphine, pethidine, physeptone, and C.B.11 are reported. Changes in threshold doses with time are discussed.

The actions of nitrous oxide and cyclopropane on ischæmic muscular pain are described.

The analgesic effects of intravenous procaine have been shown to be mainly of central origin.

Thiopentone, benadryl, neoantergan, antistin, and tetraethylammonium bromide have definite analgesic actions but are on the whole much weaker than the recognised analgesics.

Individual variations with regard to analgesic action and the development of side-effects are discussed.

We wish to thank Mr. R. M. L. Dry and Mr. J. W. Markham for their most willing coöperation and patience in this investigation; Dr. F. Prescott and Dr. R. H. Thorp, of the Wellcome Foundation Ltd., for their help in providing supplies of physeptone, Hoechst 10582, and isoamidone; Glaxo Laboratories Ltd. for supplies of C.B.11; Dr. H. O. Schild for a sample of pure benadryl; and Dr. A. S. V. Burgen for helpful criticisms.

NEBULISED PENICILLIN AND POST-OPERATIVE PULMONARY COMPLICATIONS

E. J. Holborow
M.A., M.B. Camb.

E. A. Spriggs
B.M. Oxfd, M.R.C.P.

From the Postgraduate Medical School of London

In thoracic operations for suppuration of the lung the use of penicillin inhalations to reduce the incidence of postoperative pulmonary collapse proved disappointing.[1] We report here the results of a similar use of penicillin in the rather different circumstances of abdominal surgery.

The patients were adults undergoing abdominal operations, including herniorrhaphy. Each was examined at least a day before operation and assessed as a "chest risk"—good, moderate, or bad. In each of these three categories alternate patients were treated with nebulised penicillin, the remainder serving as controls.

In the treated group at least three inhalations of penicillin (100,000 units each) were given in the 24 hours before operation. Further doses were given the evening after operation and the next morning. Since it was found t penicillin-sensitive organisms usually took 48 hours more, after inhalations were stopped, to return to respiratory tract, and since in most cases pulmon collapse has its origin in the first 24 hours after operati this dosage of penicillin was thought sufficient a minimum. Most of the patients, however, for reas sometimes unconnected with the main experim received longer courses, either starting earlier or finish later, or both.

Bacteriological examinations were made on sw from the nose and throat, and on sputum when it c be obtained. Effective administration of penicillin, reflected in the respiratory flora, was proved for e case in the treated group.

Patients were examined daily, after operation, by same observer (E. A. S.) in all the cases. Clinical evide of pulmonary collapse or consolidation, confirmed radiology, was the criterion of complication. Pulmo embolism, uncommon in the first week after operat was outside the scope of the inquiry.

RESULTS

Bacteriology

In the penicillin-treated group the bacteriolo changes followed a standard pattern. The first sv taken after the start of inhalations gave a smaller growth than the initial swabs. On the day of opera the upper respiratory tract was often superficially al sterile, and any penicillin-sensitive pathogens which originally been demonstrated—e.g., β-hæmolytic stre cocci, *Strep. pneumoniæ*, *Staph. aureus*—could no lo be grown.

After two days' inhalations the multiplicatio penicillin-resistant bacteria was usually advanced. T were predominantly organisms of the coli-aerog group, usually in pure culture, but sometimes associ with *Hæmophilus influenzæ* or other resistant bact Return of penicillin-sensitive organisms while inhalations continued was not observed. Multiplicat of neisseria strains sometimes either preceded or acco panied the appearance of coliforms, but these were relatively insensitive to penicillin, requir concentration of 4–6 units per ml. for inhibition in vi

Similar changes were observed in those cases of treated group which had pulmonary complications.

Complications

The incidence of pulmonary complications was follows:

	Treated	*Controls*	*Total*
Complications..	10	6	16
No complications	34	38	72
Total	44	44	88

It will be seen that chest complications occurred m frequently in the treated group than in the controls, the difference is not statistically significant.

If the administration of nebulised penicillin, amon much larger series of cases, were to reduce the numbe chest complications to half, the expected incidence complications in 88 cases would be as follows:

	Treated	*Controls*	*Total*
Complications..	$5\cdot\dot{3}$	$10\cdot\dot{6}$	16
No complications	$38\cdot\dot{6}$	$33\cdot\dot{3}$	72
Total	44·0	44·0	88

A deviation as large as that of the observed inciden from the expected incidence would occur by chance o once in 150 times ($\chi^2 = 7{\cdot}40$; $n = 1$). It is therefo understood that nebulised penicillin, as administered this series, would not substantially reduce the incide of chest complications.

[2] Stringer, P. *Lancet*, 1947, i, 289.

[illegible] attacks about every hour, precipitated by speaking or eating. He had one brother who had also had trigeminal neuralgia.

He showed no abnormal physical signs apart from the fact that he was obviously having periodic severe pain, for which he got relief by rubbing his face to the extent of producing conjunctivitis on this side. He was generally [illegible].

Under a course of injections of cuprelone the patient [illegible] improved (fig. 2); he was discharged having lost his pain and now twelve months later he has remained more or less free from pain.

Case 3.—A housewife, aged 66, had had severe intermittent pain of the right side of the face for 12 years, brought on by eating, washing, removing the denture, or talking. Occasionally the attacks appeared to arise spontaneously. The present attack began 6 weeks before, and had continued up to admission to hospital in July, 1947. Through the whole course of her illness the patient had never had a remission of pain for more than 3 months.

There were no abnormal physical signs, except a slight loss of weight owing to the difficulty in eating. There was a definite trigger point for production of pain on the upper lip at the junction of the lip with the nostril.

The patient improved with a course of cuprelone injections (fig. 3), and was discharged free from pain. A year later she wrote that she had never felt better.

Case 4.—A housewife, aged 71, had had severe pain in the [illegible] side of the face 4 months before admission to hospital in [illegible] 1947, followed by severe attacks of burning pain in the [illegible] side of the face, typical of trigeminal neuralgia and brought on by rubbing, touching, and eating. In her previous history, the only important factor was that she had had gout.

No abnormal physical signs were noted, and the patient was not so severe a case as the three previous ones. Her general condition was good.

After a course of cuprelone injections (fig. 4) she was discharged free from pain: 3 months later her doctor wrote that she had had a relapse, which had responded to a sedative mixture.

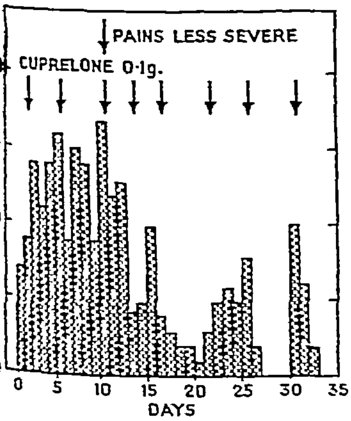

Fig. 3.—Trigeminal pain treated with a total dosage of 0·8 g. of cuprelone in 33 days (case 3).

DISCUSSION

In these four cases the injection of cuprelone was followed by relief of pain: in some cases single injections of 50 or 100 mg. seemed satisfactory; in others more distinct relief followed a course of injections of 800 mg. in 6 weeks. All the patients were satisfied that the injections had materially lessened the number of their attacks and the severity of their pain. In a case of malignant bone disease cuprelone did not relieve the pain.

In case 1 an injection of distilled water had no effect on the pain, though the patient was unaware that there had been any change in the injection. In this case cuprelone relieved the pain as satisfactorily as did trilene. The dosage has been varied experimentally, and a higher dosage may possibly be given without ill effect. Case 1 showed severe paræsthesiæ in the legs in the middle of the course, and this may have been caused by copper. There has been no evidence of leucopenia or of renal damage. Of these four patients three remain well 6 months later, but one has relapsed.

Cuprelone has been tried in nine other cases. In one it appeared to have no effect, and in two the effect was doubtful, but in six the result appears to have been satisfactory, and it is felt that the action of cuprelone is worth further study. It may have specific effects on the trigeminal-nerve nucleus, as triethylene and stilbamidine appear to have. If this is true, a modification of the drug in structure and dosage may play a useful part in the relief of a painful malady.

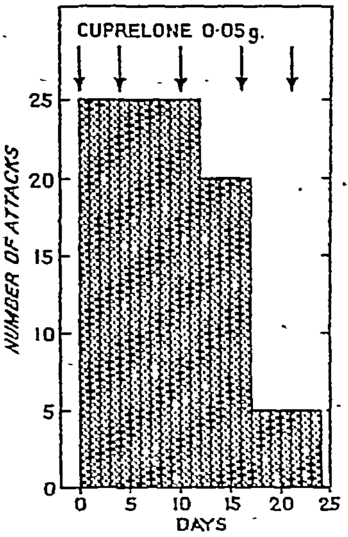

Fig. 4.—Trigeminal pain treated with a total dosage of 0·25 g. of cuprelone in 30 days (case 4).

SUMMARY

Intravenous injections of cuprelone have been given in thirteen cases of trigeminal pain, and in some of them the pain was relieved.

Toxic effects were negligible.

Owing to psychological factors, the results must be interpreted cautiously.

Cuprelone may possibly act directly on the trigeminal nucleus.

My thanks are due to Bayer Products Ltd. for supplies of this drug.

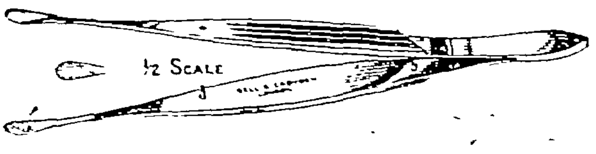
New Inventions

DISSECTING FORCEPS WITH SPATULATE ENDS

THIS dissecting non-toothed forceps is a modification of McIndoe's forceps and is adapted from the patterns commonly in use in the United States. It is useful for holding intestines during anastomosis and also in suturing the various layers of the abdominal wall. As the cross-serrated spatula-like ends do not injure the tissues when used during dissection or suturing, it has many advantages over the ordinary forceps employed today.



The forceps has been carefully made to my instructions by John Bell & Croyden, London.

RODNEY MAINGOT
F.R.C.S.
Surgeon to the Royal Free Hospital and the Southend General Hospital.

"... The great French clinicians of the nineteenth century taught, as a matter of course, that there were two stages in the development of alcoholic cirrhosis. The first, in which the liver was enlarged and infiltrated with fat, they called steatosis of the liver: the second, in which the organ was small and fibrotic, they termed portal, atrophic, or Lænnec's cirrhosis. For some reason this knowledge did not take root and withered under the sterilising error which conceived hepatic fibrosis as a single entity—cirrhosis of the liver—instead of the similar end result of different initial injuries."
—Prof. H. P. HIMSWORTH, *Science Progress*, 1948, 36, 577.

Preliminary Communication

TRIGEMINAL NEURALGIA TREATED WITH CUPRELONE

IN the late war the Germans produced a copper compound of low toxicity to serve as a substitute for gold salts. This substance, cuproallyl-thiourea-sodium benzoate, which contains 19% copper, is now manufactured in this country under the name of 'Cuprelone' and is obtainable in dry ampoules containing 10 to 100 mg. The powder is dissolved in sterile distilled water for intravenous injection. The salt is secreted in the liver and most tissues show an increased copper content after its administration. Excretion is slow and may last two months.

van Ravesteyn[1] gave the salt intravenously in 100 mg. doses (19 mg. of copper) and produced a rise in the blood-copper level for two hours after the injection. Probably all the extra copper is excreted in the next two or three weeks.

The observations made by workers that copper was useful in preventing swayback, a demyelinating disease of sheep, led Campbell et al.[2] to try copper sulphate in the treatment of disseminated sclerosis, without success. Copper sulphate had the disadvantage of being a gastric irritant and in some cases it caused vomiting and had to be discontinued. The introduction of cuprelone offered an organic copper salt which was free from this disadvantage; so it has been tried in disseminated sclerosis. Although there has been little evidence of improvement in this disease, it was noted in a patient with disseminated sclerosis who also had severe trigeminal pain, that the pain was alleviated immediately after an injection of cuprelone.

On the basis of this observation cuprelone has been tried in a few cases of classical trigeminal neuralgia, and in some of them there appeared to be a decrease in the number of attacks and a lessening of pain. Trigeminal neuralgia normally waxes and wanes and may ofte improve on admission to hospital with rest in bed; but even when allowances have been made for this, it i considered that some cases responded satisfactorily t intravenous cuprelone. The cases have been assesse by charting the number of attacks of pain agains the time in days (figs. 1–4). This shows a response bot to a series of injections and to single injections. Th results, though varied, are thought worthy of publicatio

CASE-RECORDS

Case 1.—A male casemaker, aged 43, first attended t Bristol Royal Infirmary in January, 1947, with severe shooti pain in the left side of the face and lower gums. He had first noted severe pain when washing his face, and this had persisted ever since, with anything up to 30 attacks a day, precipitated by eating, washing, or speaking. The patient appeared to have a typical trigeminal neuralgia, and he was obviously frightened of speaking and moving the lower jaw. Ten years earlier he had suddenly lo the vision in his right eye; this had lasted 6 weeks and th completely recovered. For $3^1/_2$ years he had noted increasin stiffness in both legs and had been treated by his doctor fo rheumatism. It was only when the severe pain in the fa began that he was forced to attend hospital.

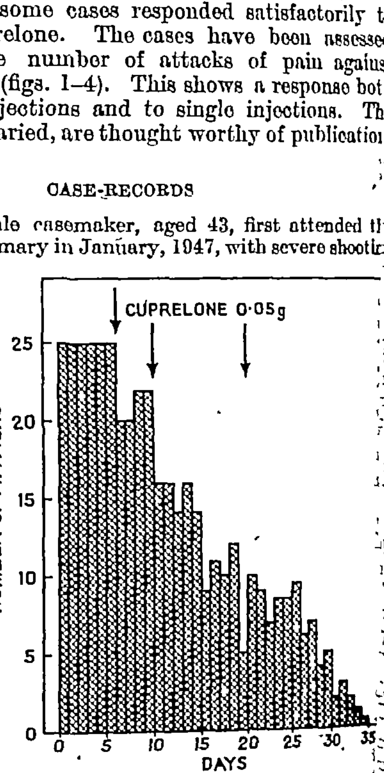


Fig. 2—Trigeminal pain treated with a total do of 0·15 g. of cuprelone in 35 days (case 2).

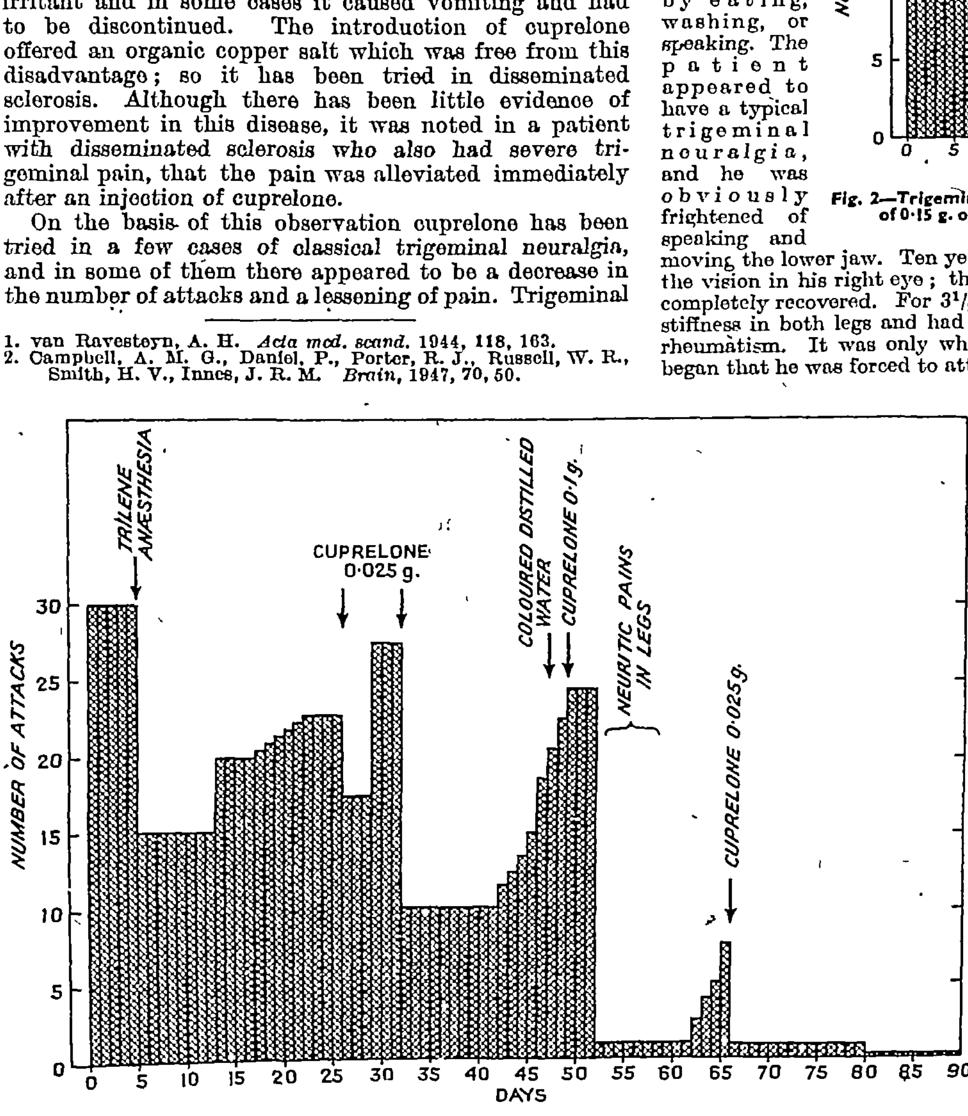

Fig. 1—Trigeminal pain treated with a total dosage of 0·175 g. of cuprelone in 90 days (case 1).

He had nystagmus o looking to the right, an there was spasticity of bo legs, with increased reflexe plantar reflexes bein equivocal on the left an extensor on the righ Disseminated sclerosis w diagnosed, and the trigem nal pain was considered t be due to a plaque involvin the fifth-nerve nucleus.

Fig. 1 shows that th patient reacted satisfactoril to 'Trilene' and later t cuprelone injection Towards the end of th treatment he had para thesiæ in the legs, probabl a result of the copper inje tions. Apart from this h urine, blood-count, and cere brospinal fluid remained normal throughout treat ment. Follow-up shows tha he has had no return o pain in the year and a hal since treatment.

Case 2.—A baker, aged 79, had had severe pain in the right side of the face for 30 years, with periods of freedom, but becomin more severe lately. In April, 1947, he was

THE LANCET

LONDON: SATURDAY, OCT. 30, 1948

Blood for Transfusion

The National Blood Transfusion Service has lately been criticised in our correspondence columns on the ground of failure in its primary task, which is to supply blood in sufficient quantities, and of the right groups, to hospitals and other users. Like most other organisations at the present time, the service is of course capable of improvement; and there have been big difficulties to overcome in many areas. But there are already considerable achievements to its credit, and the collection of blood has much improved, especially in certain areas For example, in the area covered by the two London blood-supply depots 36,522 donors were bled in the second quarter of this year, compared with 22,366 in the last quarter of 1946; and for the whole of England and Wales the figure rose from 65,532 to 98,055.

The panel of donors in England and Wales on June 30, 1948, showed an increase of about 110,000 over the figure for Dec. 31, 1946, and represented some 75% of the estimated optimum, assuming that donors are bled only twice a year. Certainly many more donors are needed; but it seems improbable that the methods used in France, as described by Dr. Piney, would meet with much success in this country. The issue of chits to enable donors to buy extra rations amounts almost to payment; and, as Dr. Popham points out, this form of inducement might have to be replaced, when rationing ceases, by a cash equivalent, which would finally kill the voluntary spirit. Moreover, experience suggests that most of those who say that lack of good food prevents their giving blood—and this reason is rarely given—are in fact people who are already receiving extra rations by reason of their employment: the excuse is but seldom heard from the overworked and comparatively underfed housewife. The only tangible reward at present received by the donor is a neat booklet—rather like the pre-war driving licence—and a certificate for each donation. In addition he is in future to be issued with special badges after ten donations, after twenty-five, and after fifty. But it is questionable whether these badges will be much displayed, for most donors are self-effacing and unemotional about their contribution; and the appeal to sentiment, used with considerable success during the war, is now best replaced by a straightforward account of what blood-transfusion can do, and to what extent the hospitals rely on the help of local donors. To this end the National Blood Transfusion Service has lately begun to issue to all donors, when they give blood, a small illustrated brochure setting out the facts and appealing for increased support The aim has always been to make the giving of blood an informal occasion; sessions, whether held in hospital wards, village halls, or factory canteens, have the atmosphere of a tea-party. More can and should be done on these lines. Surely it is high time that A.R.P. stretchers, wooden trestles, and drab Army blankets were replaced by equipment more pleasing to the eye and more fitting to a permanent peace-time service. The time has come, too, for the nurses and drivers to be given a distinctive uniform.

Though the demand for blood would doubtless be greater if there were unlimited supplies, the National Blood Transfusion Service can claim at least to be meeting essential needs, since the number of bottles collected during the June quarter exceeded the number used by almost 21,000. Most of this excess was made into dried plasma, and a large proportion was "carried forward," for issue during the next quarter. Any shortages, therefore, are likely to be temporary and local, and particularly of group-O blood; for more than half the blood issued is of this group. To relieve this difficulty, hospitals might well improve their arrangements for blood-grouping, so that wherever possible homologous-group transfusions were given. It might be feasible to determine the ABO group and Rh type of every patient on admission. so that only a cross-match would be required when blood was given; and group-O Rh-negative blood, which is apt to be scarce, could be reserved for patients who must have it. The success that regional blood-transfusion officers have had in persuading hospitals to use homologous blood is evident from the fact that in the past twelve months the proportion of group-O blood has fallen from 60 to 53% of the total issued, while the proportion of Rh-negative blood has risen from 4·5 to 9·2% of the total. One of the aims of the service since mid-1946 has been to encourage, and (where necessary and possible) to perform, Rh tests on women before childbirth; and since the last quarter of 1946 the number of tests made quarterly by the service has risen from some 26,000 to over 56,000—an increase of about 112%. Another aim has been to encourage the use of concentrated or packed red cells for the treatment of anæmias, and between the last quarter of 1946 and the second quarter of 1948 the blood employed for these preparations rose from 1469 to 3452 bottles—an increase of 135%.

In the United States and Canada relatively more blood is used for transfusion than in this country, and no doubt the demand here will grow. As this happens, it will be increasingly important for consultants and housemen to see that blood is used only when it is really needed. There is undoubtedly some wastage from indiscriminate transfusion, blood being given without sufficient indication that it may really benefit the patient Even more wasteful is the practice of ordering an unreasonable number of bottles, to be cross-matched and set aside against the patient's later need; often these bottles are held in reserve until the expiry date and are never used. Both these causes of waste would be largely eliminated if replacement involved something more difficult than a telephone call to the nearest regional transfusion centre, and if all those who ordered transfusion remembered that they are handling a gift made at sacrifice of time and energy. Dr. Popham in our issue of Sept. 25 urged that more should be done to

Reviews of Books

Cardiography

WILLIAM EVANS, M.D., D.SC., F.R.C.P., physician to the cardiac department, London Hospital. London: Butterworth. 1948. Pp. 132. 25*s.*

Dr. Evans's book is in two parts, the first dealing with the common abnormalities of the electrocardiogram and the second with records of heart sounds. The electrocardiograms illustrating the first section are accompanied by a minimum of text and little or no theory as to the mode of production of cardiographic changes, but the student who applies himself to the tracings and description will gain a first-class introduction to the subject. The second section, on phonocardiography, is very largely the original work of the author, who has done much to clarify and advance this aspect of cardiology. The special value of this method is in the diagnosis of some valve lesions, and, according to Evans, in its ability to distinguish the innocent from the significant murmur, and to classify added heart sounds. The subject is still in an early stage of development, but this account is the clearest and most rational we have seen. The conclusions drawn are based on very extensive observations, and whether or not they are confirmed by further investigations they will certainly prove a valuable stimulus to further work.

The records illustrating both sections of the book are nearly all of flawless quality.

Recent Advances in Surgery

(3rd ed.) HAROLD C. EDWARDS, O.B.E., M.S., F.R.C.S., surgeon and lecturer in surgery, Kings College Hospital London. London: J. & A. Churchill. 1948. Pp. 437. 24*s.*

NEARLY twenty years have passed since the second edition of this book was published, and Mr. Edwards must have found it hard to select the subjects for his new one. His choice will be generally acceptable. Possibly a more satisfying treatment would have been to cut down the number of subjects and go into them a little more deeply, but the student preparing for an examination will no doubt prefer the arrangement as it is. The alimentary tract claims the largest section of the book and is well covered. In addition to this section, and a preliminary chapter on general subjects including the healing of wounds and fluid balance, Mr. Edwards himself has been responsible for a section on diseases of blood-vessels and a miscellaneous one dealing among other things with the thymus and the prostate. Three other authorities contribute chapters on the more specialised branches of surgery: Mr. R. C. Brock on the thorax (confining himself to the surgery of the heart and bronchial carcinoma); Mr. D. W. C. Northfield on neurosurgery; and Sir Stanford Cade on the radiotherapy of malignant disease. Altogether this is a most useful book, not only for the student but also for the busy practising surgeon who must keep up to date.

Practical Bacteriology, Hematology, and Parasitology

E. R. STITT, M.D., PH.M., SC.D., LL.D., surgeon-general, U.S. Navy, retd; PAUL W. CLOUGH, M.D., physician-in-charge, diagnostic clinic, Johns Hopkins Hospital; SARAH E. BRANHAM, M.D., PH.D., SC.D., senior bacteriologist, National Institute of Health; and contributors. London: H. K. Lewis. 1948. Pp. 991. 50*s.*

IT is ten years since the previous edition of this well-known practical textbook appeared and it is not surprising that in some respects this tenth edition is almost a new book. Still of reasonable size and price, it remains a remarkable compendium of facts and figures that the clinical pathologist and physician need to know but cannot always carry in their heads. The new bacteriology section contains many good tabular summaries. The nomenclature adopted is that of the 6th edition of Bergey's Manual, except in the case of the salmonellas. Up-to-date techniques, like the yolk-sac material method for distinguishing the different rickettsiæ, are fully represented; and it may be noted that infective hepatitis and homologous serum jaundice are placed among the filtrable virus diseases. The section on medical mycology is a well-illustrated account of a group of conditions some of which are rare in this country. Hæmatological method are well described, and the authors are decided abou which they think best: the modified Neubauer ruling preferred for hæmocytometry, and either a photo-electr colorimeter or a Sahli instrument for hæmoglobinometr Most American textbooks have given up Haldane method now. The illustrations, except for the plate showing the blood picture of monocytic leukæmia, are not very good, and the explanation of the hæmorrhagic diseases seriously out of date.

The tropical and parasitology sections, and those th deal with insects, poisonous snakes, and fish, are as go as before, and there are some first-class plates of malari parasites. A new section on vitamins is provided; an a useful table sets out the variation of some importa constituents of the blood—such as urea, sodium, an calcium—in various diseases. This is a welcome revisi well able to take the place of its predecessor.

Post-Mortem Appearances (5th ed. London: Oxfo University Press. 1948. Pp. 308. 8*s.* 6*d.*).—This practic little pocket-book has been extensively and well revised maintain its usefulness as a guide to students and those havi to perform autopsies without advice and assistance. Dr. Ja Ross is as concise, lucid, sound, and practical as ever, and h book contains a remarkable amount of information couch in good terse English.

An Apple a Day (London: Cassell. 1948. Pp. 1 10*s.* 6*d.*).—Those who have read *Go to the Country* and ha discovered Dr. Philip Gosse's humour and joy in natu sights and sounds will be prepared for this successor. narrates his professional success and non-success with equ gusto. (His habit of taking a long holiday after an uneq contest with his professional examiners must be noted, b whether this was of a consolatory character, or, in his mi a reward for work well done, he does not specify.) The bo as a whole is an odyssey of adventure, taking us all over t world; but it is also full of wise sayings and bears the star of a keenly observant outlook. Dr. Gosse notes and commen tellingly on many apparent trivialities in life which m of us take for granted. There is a certain carefree irrespon bility about him which gives his book an atmosphere a charm of its own.

The Way to Natural Childbirth (Edinburgh: E. & Livingstone. 1948. Pp. 124. 7*s.* 6*d.*).—Since Dr. Gr Dick Read published *Natural Childbirth* over fifteen y ago a new school of obstetrics has arisen. It is healthy th the technique of an unorthodox clinical method should b elaborated by enthusiastic disciples, and Mrs. Helen Heardma is evidently one of them. She practises and writes a physiotherapist who has become interested in obstetrics, an this approach carries a risk of emphasis on a meticulo régime of physical preparation. In their written form, h instructions have an austerity which would disturb the sens tive minds of many expectant mothers; while some of th illustrations would certainly upset all anatomists. Neverthele the book should be useful to the teacher, and especially th physiotherapist of an obstetric unit; for, though it is large a synopsis of the work of others, it also describes the author own experience, both personal and professional.

Malaria Control by Coastal Swamp Drainage in We Africa (London: Ross Institute of Tropical Hygiene. 194 Pp. 97.).—Before and during the early days of the war, Apap in the urban area of Lagos was notoriously malarious. vessel making a stay of only one night alongside Apap wharf would, within a couple of weeks, have many of its crew down with fever, and 80% of all ranks of an anti-aircraf battery stationed there in 1942 contracted malaria within thre months of their arrival. Extensive swamp-drainage scheme and mosquito control by engineering methods were instituted by the Services, and matters began to improve. Within comparatively short time malaria had ceased to be an almost invariable sequel to a visit to the area, and in a year or two it became relatively rare. In this small volume Dr. A. B. Gilroy, now principal of the India branch of the Ross Institute, gives an account of the problems confronted and of the methods whereby this very considerable achievement wa reached. It is well illustrated by lively diagrams, plan drawings, and fine photogravure plates, and will be valuable to all concerned with like problems.

peculiar that it can find only one type of cell into which it can fit. Such a conception, after all, is accepted for the interactions between antigen and antibody. Complete specificity of this kind may later be lost through adaptations to other cells of the same host or to other hosts. Moreover, just as a cell adapted to produce antibody globulin of a particular type transmits this property to its descendants, so the later generations of an adapted virus can reproduce the new shapes first learned by their enterprising ancestor.

At the risk of over-simplification, we may say that many features of infection specificity probably depend on whether food is both available and accessible to the parasite. If an innkeeper wants to offer true hospitality to a fastidious guest of unusual proportions he will see to it that the guest's favourite meal is on the table, but he will not think his duty discharged until he has provided a chair of a size and shape that will allow his guest to reach the table in comfort. Nor, while his guest is eating, will he fill the room with stick-at-nothing ruffians who make no secret of their desire for a square meal of the kind on the table. If the establishment fails in such matters, the innkeeper need not expect his guest to stay, and still less to call again, recommend the place to his friends, or enjoin his children and grandchildren to confer their exclusive patronage on the hostelry in memory of the services afforded him.

Return to Philanthropy?

It is presumably inevitable that with our advance towards social security, sponsored by the State, some of the light should seem to fade from voluntary [illegible]. Now that we have attained to social insurance [illegible], and so much else, the giant evils of the past [illegible] to look less formidable, and many of those engaged in voluntary effort may even feel a little [illegible]. By contrast with the enthusiastic gatherings of the hospital contributory scheme of a decade ago, the meetings of a regional board may seem to lack the old zest. Yet, at least in the National Health Service, the volunteer has opportunities of usefulness as great as any in former days. And we know that loneliness and failure and misery will still demand help of many kinds, despite all the State can do.

Into this field Lord BEVERIDGE has moved in his latest report entitled *Voluntary Action.*[1] Having been reluctant to see the approved societies by-passed in the administrative machinery of social security, he has now collected a group of helpers and has produced a readable survey, not only of mutual insurance in all its forms, but also of the much wider subject of philanthropy today as it passes from the old world into the new. The first section of his inquiry is concerned with the motive of mutual aid, mainly as illustrated by the history of the friendly societies. He believes that there will still be a large scope for insurance above the minimum: it is likely that the societies will find a strong desire for higher benefits in sickness, above what the State gives, and especially during short periods of incapacity. A long section entitled "The philanthropic motive in action" traces the controversy between ARTHUR HOBHOUSE and JOHN STUART MILL on the reconciling of testators' wishes with the public interest. HOBHOUSE held that the public, in dealing with charitable trusts, must have the right to decide the particular use to which a testator's benefactions are to be put, and that there must always be "a living and reasonable" owner of property to manage it according to the wants of mankind. Taking HOBHOUSE's view as his criterion, Lord BEVERIDGE passes in review the work of the half-dozen great general trusts—the Nuffield Foundation, the Pilgrim Trust, and the others, and, in its slightly different category, King Edward's Hospital Fund for London. These trusts fulfil the necessary conditions, he says. They earn his approval; and indeed what other verdict could possibly have been given? But when he comes to deal with the older and numerically much larger group of miscellaneous charities he strikes a different note. The time has come, he thinks, when the mild and legalistic approach embodied in the powers of the Charity Commissions should be replaced by a much more radical plan. Might not many of the older charities be swept into the net and redesigned to meet current needs? Definite recommendations are made. The appropriate authority should have power, with the consent of the charity concerned: (1) at any time to make a scheme for its administration on the cy-près principle; (2) after fifty years to make a scheme for the use of gifts, within the broad category of the original gift; and (3) after a hundred years to make a scheme for the use of the gift for any charitable purpose which may seem expedient. In discussing the lacunæ of a "social service State" Lord BEVERIDGE rightly gives prominence to the needs of age—housing and special homes—and the need for a new approach in the medical treatment of the aged. The British Medical Association committee's report is quoted with approval, with the emphasis on geriatric departments and the possibility of discharge of many of the patients to appropriate accommodation outside the hospital service. "The picture presented in this chapter is a grim one. It is a picture of unhappiness of many different kinds, with relieving agencies working against odds. The unhappiness is not due primarily to want of money; it has not been, and will not be, remedied by redistribution of money." Two practical conclusions emerge: first there must be adequate diversion of physical resources, and secondly the voluntary agencies must have the material resources to enable them to do their work. How they are to obtain these resources in the changed economic and social conditions is "one of the critical problems of the future."

Whether or not Lord BEVERIDGE's more specific recommendations are adopted, there is no doubt of the value of the survey as a corrective to much loose—or should we rather say unpractical?—thinking on the part of those who have believed that responsibility can be shifted to the State and that all will then be well. This tendency in popular thought can be traced in no small degree to the Liberal-Fabian-Socialist school of which Lord BEVERIDGE has himself been such a prominent exponent. That he should now stand back and take stock, and say plainly that the social security for which he has worked is no open sesame, and that voluntary effort enlist the help of patients' relatives, who are often willing to join a panel and replace the blood used. But he rightly said that this kind of effort cannot be made by one person, for it requires the interest and support of the whole hospital staff. Interest and support are in fact the outstanding needs of the whole blood-transfusion service, and criticism comes best from those who help it most.

Specificity of Infection

A GOOD understanding of the pathology of infection cannot be gained without studying the part played by the host. In a natural desire to exploit new methods of examining the physiology and biochemistry of bacteria and viruses this has sometimes been forgotten, and we therefore welcome the timely message of Professor WILSON SMITH's presidential address last week to the Royal Society of Medicine's section of comparative medicine. He has rightly redirected attention to the unsolved puzzles of host and tissue specificity in infections. Why, for example, is the leprosy bacillus unable to grow except in man? Why is the Algerian sheep resistant to anthrax while other sheep are susceptible? Why do some people have several colds a year while others escape?

These questions have fascinated their students ever since EHRLICH's brilliant observations, deductions, and guesses started the debate which still continues; and knowledge of them has now reached a stage when a reasonable amount of theorising offers the best chance of designing the crucial experiments required. In broad terms, as WILSON SMITH pointed out, specific associations of infecting agents with species, races, individuals, tissues, or cells depend on whether the host cells can participate in biochemical reactions with the infecting parasite or its products. "Extrinsic" factors may decide or influence the issue: for example, the right or wrong portal of entry; the presence or absence of an essential vector; whether the host's nutrition is good or bad, or his metabolism active or sluggish; whether the host has had previous contact with the infecting agent; and whether his body fluids stimulate or suppress the invader's growth. About some of these factors a fair amount is known, and others are being purposefully investigated. But "intrinsic" factors, intimately connected with cell structure and function, are more difficult to explore, and it is about these that speculation is most required.

To make a start with our guesses, we may profitably consider some of the recent discoveries about viruses. The association between a virus and a host cell it has parasitised is particularly close; indeed the virus cannot grow in nature or in artificial culture unless it is able to enter a living cell. It is of great interest, therefore, to learn that between some viruses and cells specificity of association does not depend on the whole cell or virus but on a particular component. Thus both living and heat-killed influenza virus can agglutinate the red blood-cells of the chick; but the next reaction, elution of the virus from the cell, is not accomplished with heat-killed virus, because this has lost the enzyme required to disintegrate the part of the red cell (the receptor) which holds on to the virus. If red-cell receptors for influenza virus are destroyed by treatment with *Vibrio choleræ* mucinase, the virus cannot be adsorbed to the cell and the cell cannot be infected.[1] It is a fair guess that the transient insusceptibility observed with some viruses may coincide with the stage when the cell, having rid itself of infecting virus and specific receptor in a single act (elution), cannot be reinfected until it has regrown its receptors. Among bacteriophages, which may be accepted as viruses for our argument, specificity is narrowed even to variants of a single strain of bacteria. A culture of bacterial host cells susceptible to lysis may be readily transformed to one in the insusceptible state, and the change may depend on loss of specific cell receptors or on their being masked by new components, as in the loss or gain of an antigen. Inactivated phage, by blocking specific receptors on the host cell, may prevent lysis by active phage whose attachment has been made impossible by the "interference" of the inactivated phage. This perhaps explains how modified viruses may act as specific immunising agents against virulent forms of their own strain, and may sometimes confer insusceptibility on others whose demonstrable relationship is remote. But simple blockage of cell receptors will not explain all we know of bacterial insusceptibility to phages, and LURIA and DELRÜCK supposed that there may be competition among phages for a single key enzyme present in the host cell in such small amount that it may be deviated by even one particle of inactivated phage.

The lifelong resistance to reinfection conferred by some viruses probably depends on continuous carriage of the virus in the host cells and its transmission to daughter cells—a phenomenon well established for lysogenic strains of the bacillus group which transmit phage to cells arising even from their spores. If a similar perfection of cell-virus symbiosis is possible in man, the many unexplained transient fevers of childhood may represent only the acquisition of [illegible] unidentified virus which, when it has settled in [illegible] appropriate place, may have an important part [illegible] play in developing general or specific resistance. We now know that viruses may enter and grow in a cell without causing much or any constitutional disturbance, especially if—as in recurrent herpes—the balance of events is not disturbed by some intercurrent infection or other upsetting event. In addition, viruses show great powers of adaptation if they are given enough opportunity to parasitise a new host or tissue. This was well shown in the gradual adaptation of human influenza to the mouse via the ferret. From the ferret adaptations were also made to the guineapig and rat, and in these species the infections were symptomless. Similarly with rinderpest virus, strains were adapted from oxen to goats and rabbits, and the infectivity for oxen of a strain undergoing goat adaptation was found to depend on the number of goat passages it had undergone—remarkable evidence of the plasticity of the virus and of a quantitative aspect to the process of adaptation.

Putting all these guesses together, WILSON SMITH argued that infection, with all its enzyme interactions, requires physical linkage of virus to host cell, and that this is possible only if the molecular configurations of virus and cell allow close enough apposition. The explanation of complete specificity may well be that the virus has a surface shape so peculiar that it can find only one type of cell into which it can fit. Such a conception, after all, is accepted for the interactions between antigen and antibody. Complete specificity of this kind may [illegible] be lost through adaptations to other cells of the [illegible] host or to other hosts. Moreover, just as a cell adapted to produce antibody globulin of a particular type transmits this property to its descendants, so [illegible] later generations of an adapted virus can reproduce the new shapes first learned by their enterprising ancestor.

45, falling a little to 167,210 in 1946. The apparent repancy between this increase and the downward d of major accidents is probably explained, says the port, by "factors such as more regular employment ing the war years, the incidence of P.A.Y.E., higher s of compensation benefits, a greater tendency to d minor accidents more seriously, and the higher erage age of the employees."

Discussing the growing preoccupation with dust pression, the report cites the South Wales area, here by the end of 1946 almost 600 miles of steel water-pes had been installed underground for this purpose. The report also refers to first-aid arrangements as often atisfactory, usually for the reason that no suitable son is in charge; septic infection of minor injuries— common, though less of a problem than formerly ould be reduced with better equipment and more ly trained personnel. *In point of fact* a scheme for e erection and expert staffing of treatment centres at es was initiated towards the end of the period under iew. The concession, arranged in 1944, by which ined first-aid workers may administer morphine in ergency, has proved to be a wise one.

STREPTOMYCIN RESISTANCE AND DEPENDENCE

In talking loosely of organisms developing resistance lay ourselves open to a charge of Lamarckism, for resistance is not developed but unmasked. It is now ar that the appearance of strains of tubercle bacilli other organisms resistant to streptomycin results m selection of naturally occurring hereditary variants. hen streptomycin is added to a culture of organisms, ther in the body or in the laboratory, a culture medium formed which is selective for the growth of resistant riants. The facts that these resistant organisms are ly genetically stable and are present only in small ers in a random population support the view that re produced by mutation regardless of the presence drug. But how can we explain that some strains ganisms require streptomycin for growth? Miller Bohnhoff[1] obtained a streptomycin-dependent in of meningococcus, and Paine and Finland[2] e found streptomycin-dependent variants of staphylo-i and coliform organisms. Spendlove and his eagues[3] have described a strain of *Mycobacterium culosis* which grows much better when streptomycin added to the culture medium; this strain was isolated m a patient whose infection progressed rapidly during eptomycin therapy.

The full explanation of streptomycin dependence and stance must necessarily await understanding of the chanism by which the drug exerts its antibacterial ect. Dependence on streptomycin appears to be ch more labile than resistance, but Paine and Finland nt out that dependence and resistance may be closely ated traits. They found that both sensitive and pendent organisms were present in the same pre-minantly dependent colony which appeared after initial exposure of a sensitive strain to the anti-otic. Under appropriate conditions dependent variants ve rise only to sensitive organisms, and the same ncentration of streptomycin that completely inhibited he growth of the parent sensitive strain was necessary r the growth of its dependent variant. If strepto-mycin acts by blocking an essential metabolite or zyme system, then it seems more than coincidence that the concentration of drug which inhibits the sensitive rain should also make for growth of the dependent riant. In the latter the original essential metabolite ay be replaced by some part of the streptomycin molecule which closely resembles it. In the resistant variants an alternative mechanism may function in place of the metabolite or enzyme system that is blocked by streptomycin in the sensitive strain. As Paine and Finland point out, both dependent and resistant variants grow much more slowly than their parent sensitive strain, and this may be why streptomycin-resistance is often not encountered until late in a course of treatment.

ASIATICOSIDE IN LEPROSY

THE small umbelliferous plant, called *Centella asiatica*, or Indian pennywort, has been a traditional Indian remedy for leprosy and syphilis. About three years ago French workers in Madagascar reported that asiaticoside, a preparation obtained from the plant, was of some use in human tuberculosis. The drug is a white tasteless crystalline powder, insoluble in water, though it can be made soluble by oxidation with potassium permanganate. No further information on the subject appeared at the time, and we understand that some in-vitro tests of the drug in this country against *Myco. tuberculosis* were disappointing. Two French workers, Boiteau and Saracino,[1] have now reinvestigated the therapeutic possibilities of asiaticoside and claim that it is of considerable value in the treatment of leprosy and lupus erythematosus in man and of experimental tuberculosis in the guineapig. Without giving the number of cases treated, they mention remarkable results obtained in a Madagascar leprosarium. All forms of leprosy—lepromatous, neural, and tuberculoid—are said to have shown clinical and symptomatic improvement, and the causal organism, *Myco. lepræ*, disappeared from mucous lesions within a fortnight. Eight of the lupus cases were treated with asiaticoside by intramuscular injection. The first few injections apparently produced an exacerbation of the lesions, which finally cleared and underwent epithelisation after two months' treatment. The drug appears to be relatively non-toxic, the only side-effects noted being a slight fall in blood-pressure and a heavy feeling in the limbs.

In view of the legion of remedies for leprosy that have not stood the test of carefully controlled observation, comparative studies should be made in the treatment of leprosy with asiaticoside and with sulphones such as 'Diasone' and 'Sulphetrone,' which seem to be the drugs of choice at the moment.

THE BALLISTOCARDIOGRAM

LYING in bed, some people are uncomfortably aware, particularly with overaction of the heart through emotional disturbance or after stimulating drugs, that with each heart-beat their whole body moves. Actually movements of this sort take place in all of us, and their nature and extent can be measured by getting the subject to lie on a table or bed suspended so that the motion is transmitted to fluid in a manometer. Alternatively, the movements can be converted with a high-frequency oscillometer into voltage changes, which are recorded optically. The apparatus used for making this record, known as a ballistocardiogram, has been described by American workers.[2] According to Starr and Mayock,[3] the normal ballistocardiogram has four main waves, which synchronise with ventricular systole, and smaller and more variable waves in diastole. They suggest that an abnormal ballistocardiogram indicates disease or some alteration in dynamics of the heart, as in hyperthyroidism or hypertension; and though admitting that an abnormal record has been obtained in the absence of detectable heart disease, they deny that any but a normal curve is ever obtained in a healthy young adult. One positive should be not only tolerated but actively encouraged—is this not perhaps an important turning-point? Are we perhaps standing on a watershed? May we yet hope and expect to see in the years to come a resurgence of voluntary effort, great and small, freed from the slight suggestion of antagonism on the part of the learned and enlightened who mould the thoughts of the younger generation of economists and politicians?

Annotations

INFANT MORBIDITY

Ever since the time of John Graunt, infant health has been the happy hunting ground of the vital statistician. Mortality, whose extent and nature are recorded by law, has because of its accessibility been the measure of child welfare used in innumerable studies. Yet it is morbidity, the precursor of death or serious disability, which is the everyday cause of anxiety to parent and doctor; so more precise knowledge of the incidence of illnesses in infancy, their case-fatality rates, and the chances of cross-infection is certainly required. In an attempt to supply such information, Selwyn Collins,[1] chief statistician to the U.S. Public Health Service, has analysed the results of a series of periodic canvasses of families living in different parts of the United States in the early 1930's. Broadly speaking, the morbidity experienced varied little, and the results have been combined to give a comparison of the age-distribution of the various groups of causes of sickness and death among infants in their first year.

In the U.S.A., as elsewhere, the trend in infant mortality, particularly in the later months of the first year of life, has been consistently downwards; and the death-rates at successive months thus show a sharp decrease with increasing age. Morbidity-rates, on the other hand, decline from a high rate under 1 month to a minimum in the second month and then rise to attain, about the sixth month, a new level which is maintained for the remainder of the year. More specifically, digestive and genito-urinary disorders are remarkable for their high incidence in the first few months of life, whereas the infective disorders, upper respiratory infections, measles, ear diseases, and tuberculosis all have incidence-rates which rise steeply with age. Whether this is due to the fading away of immunity derived from the mother or to the increasing risks of exposure it is difficult to say. Collins gives interesting details of the chances of cross-infection in the various infectious diseases. The risk of an infant being infected by another child in the same household is measured by the secondary-attack rate. Thus whooping-cough not only has a high incidence, particularly in the last six months of infancy, but is so infectious that of 100 infants exposed to a case in the household nearly 100 will become infected. Chickenpox is similar in its high incidence and maximum secondary-attack rate of 75–80%. In measles and german measles the secondary-attack rates are roughly 40%, while mumps, which has also the lowest incidence, never has a secondary-attack rate much above 20%.

The usual hospital and national mortality statistics give no indication of either the prevalence or the case-fatality rates of the illnesses of infancy. Collins's findings, though limited in scope, suggest that the chief causes of illnesses among infants are the common respiratory and digestive diseases, with whooping-cough and ear disease high on the list; but deaths result mainly from congenital and neonatal conditions, pneumonia, and diarrhœa and enteritis. The differences in case-fatality rate thus implied are brought out by comparing the number of illnesses of each type reported in the survey. Pneumonia, for example, causes 1 death for every reported cases; about 1 in every 25 accidents are fata whereas death follows only 1 in 100 attacks of whoopin cough and influenza, and only 1 in 500 cases of meas or ear disease. These are, of course, only rough indic tions, based on restricted evidence and complicated the therapeutic innovations of the 'thirties, but t method of relating special morbidity surveys national mortality statistics is one which we might w emulate.

GASTRO-ENTERITIS FLYING SQUAD

In what is believed to be the first venture of its ki in the world, the Hospital for Sick Children, Gr Ormond Street, London, has organised a flying squ to go to the help of institutions or others in difficult over an outbreak of *infantile gastro-enteritis*. T scheme, which is being partly financed by King Edwar Hospital Fund and has the good will of the Ministry Health, starts on Nov. 1. The squad will norma consist of up to five fully trained nurses and one doct to be taken from the team which has been work on this disease at Great Ormond Street. The prim purpose is, however, not to conduct research but fill any gap in resources for investigation and treatme and it is hoped that medical officers of health will use t service. Equipment will be carried in a lorry contain besides drugs, sterilisers and everything needed transfusions and infusions. Normally the resources the nearest laboratory will be used for bacteriologi studies; but the lorry also contains a power-dri centrifuge and other apparatus for simple work of t sort. Thus in isolated areas the unit could w independently of any hospital or institution, providi if need be, a domiciliary service.

The help of the squad, which is prepared to go a where, should be sought through the local medi officer of health or regional hospital board, or where need is acute by telephoning the house-governor Great Ormond Street (Holborn 9200).

IN THE MINES

At the best of times mining is a hazardous occupatio and the conditions of the late war, with its shortage men and materials, and its demand for greater productio were expected to aggravate the risks. This expectatio however, was only partly justified, as Mr. J. R. Felto the chief inspector, shows in his report for the seven yea from 1939 to 1946.[1] The death-rate per 100,000 ma shifts, which was 0·37 in 1939, mounted to 0·46 in 19 but after that it regressed to 0·30 in 1945 and 19 Translated into actual numbers, 783 miners were kill in 1939, 550 in 1945, and 543 in 1946. In parallel with t fall in fatalities, the rate of serious injuries decreas from 1·49 per 100,000 man-shifts in 1939 to 1·28 in 19 Analysis of the 2617 fatal or serious injuries sustain underground in this year shows that 1203 (46%) we caused by falls of ground, 660 (25%) by haulage ac dents, 295 (11%) by the use of explosives, 73 (3%) gases, coal dust, and fires, 63 (2%) by machinery, a 233 (10%) by other causes. Among the factors whic Mr. Felton suggests, may have contributed to this decli are concentration of work in smaller units with larg roads and better supervision; advances in technic knowledge; the more widespread application of pri ciples of roof control and support: greater use of ste supports; inspection; and the education and traini of miners. The record of less serious injuries, involvi three days' absence from work, is much less satisfactor The number rose from 134,072 in 1939 to 181,050

VAUXHALL MOTORS LTD., LUTON, BEDS

THERE is growing awareness of the urgent necessity f conserving the nation's man-power: and though the vention of disablement, as well as the employment of bled people, can make a contribution to this end, it is industry itself that a solution of the present wastage be found.

As a result of encouragement by an enlightened ectorate, a community of 12,000 people engaged in e medium engineering industry of motor-vehicle nufacture now enjoys its own domestic rehabilitation tre. For its foundation we acknowledge the help and idance of the pioneer organisation at Austin Motors.

A rehabilitation team has been set up consisting of sulting orthopædic and plastic surgeons, an industrial dical officer, a rehabilitation superintendent and his puty, and an industrial physiotherapist. The activities f this team, in group consultation, are centred in a cial rehabilitation machine shop, or "retraining op," run on standard production lines and accommodating up to 60 men. The scheme has been in eration since 1945, and the shop opened in April, 1946.

The shop is housed in a new building set in pleasant roundings, and features such as good lighting and rior decoration have been the subjects of special y. Here, by utilising standard machines, or bench s, modified and adapted to secure controlled range power of movement, remedial occupations and d work are prescribed for patients by the visiting ons and the industrial medical officer.

he full team visits once a week, when, at a follow-up clinic and during a subsequent round of the aining shop, all patients are reviewed, treatment is ussed, and progress is recorded.

A whole-time rehabilitation superintendent is in charge of the retraining shop. He is a trained engineer of senior status who, before taking up his duties, was given an opportunity of studying the broader social and economic aspects of the local industrial conditions and hospital services. He is responsible to the company medical officer, and his duties include the placement of all incapacitated factory personnel. He is the liaison officer between the hospital and the factory.

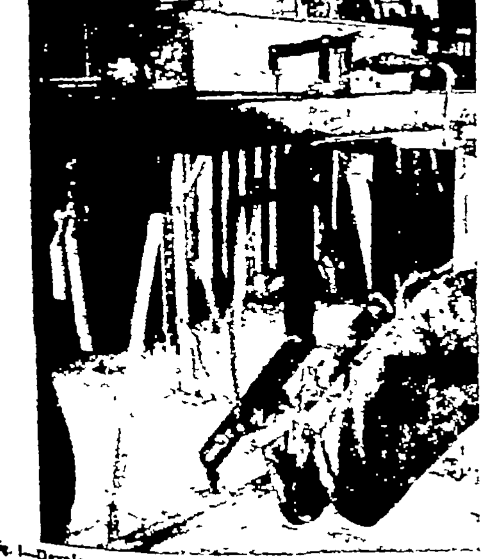

Fig. 1—Development of quadriceps muscle against graduated counter-weights at a leg-operated bench for a countersinking operation.

An assistant rehabilitation officer, selected for his abilities as a teacher of machine-shop practice, is in immediate charge of the men in the retraining shop, and his services are available if vocational training is required.

Though the scheme is intended primarily for works accident cases, disabled ex-Servicemen and employees injured away from work are catered for. The report of the Delevingne Committee showed that industrial accidents accounted for only 30% of the total; hence there is ample opportunity for rehabilitation within industry apart from purely works accident cases. Medical and psychological cases presenting difficulty in placement are also admitted for graded work until they can be accommodated elsewhere in the factory.

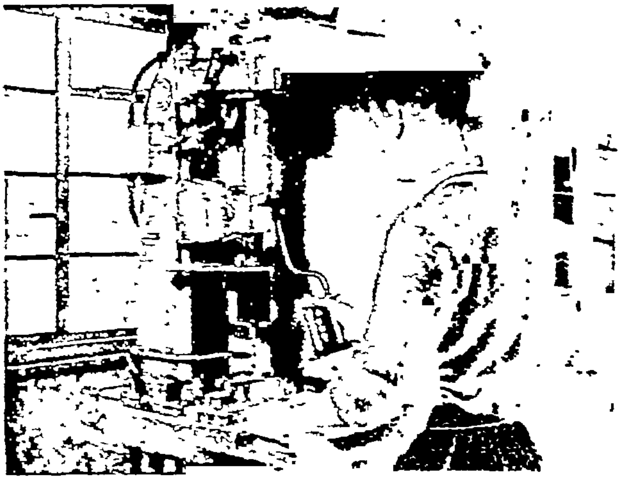

Fig. 2—Combined active and passive flexion of the fingers using a 'Sorbo'-padded and adjustable grip attached to the handle of a single-spindle drilling machine. This patient was successfully treated after primary suture of cut flexor tendons of three fingers.

In the twenty months after the shop was opened, some 452 patients passed through it. Of these, 355 (78·6%) were surgical, 72 (15·9%) medical, and 25 (5·5%) psychological. The average length of stay for all patients was thirteen weeks, and that for surgical cases six weeks. In some instances placements were preceded by a temporary trial period on selected work within the factory to ensure that the work was suitable to the patient and that the patient was acceptable to the supervision. In this connexion emphasis is placed on finding the right job rather than a light job, but in no sense is the retraining shop regarded as a refuge for invalids, and the general morale of the men has remained consistently high.

Summary of admissions

Works accident cases	257 (57%)	Medical cases	72 (15·9%)
Non-occupational cases	195 (43%)	Surgical cases	355 (78·6%)
		Psychological cases ..	25 (5·5%)
Total ..	452		

Surgical cases

Fractures	125 (35%)	Soft-tissue injuries ..	230 (65%)

Disposal

Return to full work	382 (85%)	Return to modified work	70 (15%)

In addition to the cases which passed through the shop, some 450 other placements made necessary by health observation is the finding of a distinctive curve with left ventricular aneurysm. The ballistocardiogram has also been used for measuring cardiac output[3]; indeed Nickerson and his associates claim that this technique is just as accurate as one based on right atrial catheterisation.

ORDINARY GIRLS

ALL girls are silly and ignorant, pronounced Mr. Bennet, without stopping to reflect that all he had done for his own five was to give them a silly mother and precious little education. Small wonder if they were occupied with thoughts of early marriage; and was this, after all, such a bad thing to think about? The "ordinary girls" in Miss Pearl Jephcott's study, *Rising Twenty*,[4] are in much the same position as the Miss Bennets and the Miss Dashwoods of a century ago. They are filling in time until they marry, and filling it with something more useful, on the whole, than drawing, purse-netting, and singing to the harp. Miss Jephcott's study, made in 1945–46, covers just over a hundred such girls, living in three parts of England—a pit village in County Durham, a cluster of blitzed streets near Piccadilly Circus, and a northern industrial town. They were all over 17 and under 21 when she knew them, and they talked to her of their life since they left school—" those years between 14 and 18 when, according to the stock statement which so many made, 'I learnt more than I ever did before.' "

They worked in shops and factories, and nearly all found their work boring. Life begins for them when work finishes, and they are free to spend their evening dancing, skating, or at the cinema, at first with a group of other girls and boys, and later in couples, each girl taken—and paid for—by the boy with whom she is "going steady." But this behaviour does not really justify the accusation, so often made, that these girls are "pleasure-mad." Once they get engaged they settle down quietly enough, and save up for a home. When their betrothed husbands were absent in the Army, many of the girls hardly went out at all. Marriage is their career, and almost the only career open to them which has creative aspects; and the single-mindedness with which they pursue their end would earn them praise if they were students working their way through college. They are not unaware of the heavy obligations of marriage, for they see them borne by their own parents; and some even comment on married life as "all drudgery." Nevertheless it is traditional that they must enter it, and to remain unmarried is to fail. Seen from this angle, their behaviour is perfectly logical and not at all unworthy. They must meet their future husbands, and the accepted way to do this is to go dancing. Youth clubs do not offer comparable opportunities, because there the boys are contemporaries —too young for mates and too rowdy for companions. The cinema sets their standards in appearance and hairdressing, and has on the whole been responsible for a great advance in both since the turn of the century. In the factory the girls are given dull repetitive jobs, entailing long hours of standing. Nursing, which might, if it offered more freedom, prove an attractive alternative, they reject because they believe it would ruin their prospects of marriage. They prefer the boredom and fatigue of a dead-end job because it gives them the money and leisure for their more serious duty of finding a mate. By social and biological standards they are serving the race, and doing it entirely at their own expense.

The tragedy which appears in this study is their paucity of other interests: they are not politically informed, and often fail to join a union; they chiefly read love stories, and they have few constructive hobbies. " girl who consistently tries to sing, or to dressmake to act, or to play a game, let alone to pursue anyth a shade *more out of the ordinary* than any of thes the exception." Marriage brings them new experie and skills, but debars them still more firmly f interests outside the home. Yet, limited as they ar outlook, these girls, Miss Jephcott finds, are *fu* mentally good-hearted and kindly. They take t share of the family responsibility, often giving up or two evenings or an afternoon regularly every wee mind the baby or help with washing or housework. a world with little attention to spare for the si business of living they are, in a sense, holding to fu mentals; if they need rescuing—which seems uncer —it is from the boring circumstances in which they c out their purpose. Any attempt to help them—wh on the part of youth organisations, churches, educati bodies, or juvenile employment bureaux—should directed towards enriching their lives.

SYMPATHECTOMY AND THE HEART

IT is well over eighty years since von Bezold de strated the rôle of the vagus; but other factors control heart-rate have been worked out only recently, even now the mechanism in man is somewhat obsc Cardioaccelerator nerves are generally believed to r the heart through the 2nd–5th dorsal ganglia of sympathetic nervous system; and Smithwick and colleagues[1] report that bilateral removal of these gan is followed by slowing of the rate, whose respons exercise becomes less pronounced. The effect of lateral removal is variable; and it seems that, tho the sympathetic innervation from the right side usu exerts a greater influence than that from the left, only way to ensure slowing is to perform sympathecto on both sides. Two further observations are of inter First, in a child aged 15 years, bilateral excision of 2nd and 3rd dorsal ganglia for hyperhidrosis ca "decided diminution" in pulse-rate and a le response to exercise; but the same operation i woman of 56 with Raynaud's disease had no such Secondly, in a group of four hypertensive patient whom extensive splanchnic denervation had previo been performed without effect on the heart-rate, s sequent removal of the 2nd–5th dorsal ganglia followed by definite slowing.

The variable response to unilateral sympathecto is ascribed by Smithwick and his associates to variations in sympathetic innervation. Another tion which cannot be altogether discounted is as in the dog, cardioaccelerator fibres may be in the vagus; and this would explain the oc case in which bilateral sympathectomy has little able effect. The practical implications of this are not altogether clear, but it suggests that in surgical treatment of hypertension low dorsal sympat tomy, which is liable to result in increased heart- should be accompanied by removal of the 2nd– dorsal ganglia. Possibly this operation might be use also in some cases of angina *pectoris* accompanied tachycardia, but careful assessment would first necessary. From the U.S.A. have come repeated acco of a "sympathetic syndrome," characterised by h ache, precordial pain, tachycardia, and hyperhidros here, too, a localised upper dorsal sympathecton despite its risks, might occasionally be justified.

WE regret to announce the death of Dr. C. WENYON, F.R.S., on Oct. 24, at the age of 70. Till 19 Dr. Wenyon was director-in-chief of the Wellco Research Institution.

Under these conditions men can work their way back to normal in surroundings with which they are accustomed, fully employed on a constructive job, with the stress on a system of treatment which they know can lead them back to their pre-injury status.

INDUSTRIAL OCCUPATIONAL THERAPY

For the provision of remedial movements highly skilled operations are completely unnecessary. By far the most valuable machine-tool is the single-spindle drilling machine. By adding special equipment to the operating lever most movements can be obtained for hands, arms, and shoulders. Other exercises for upper limbs are provided by the bending of copper and steel pipes round formers at the bench. Bending a $^3/_8$ in. steel rod by pulling on a 5 ft. bar gives an easy rowing motion which promotes development of the main trunk muscle groups. By adjusting the height of the lever on the machines controlled range and power can be obtained for arm and shoulder injuries. Simple bench vices operated by the foot are valuable in the early treatment of ankle and knee injuries. More intensive muscle development is encouraged on kick and pedal action riveting machines used in the closing of small tubular rivets. On such machines it is possible to obtain 9000–10,000 movements daily without fatigue. Fly presses, lathes, and milling machines make up the standard equipment, and besides these there are special pieces of apparatus capable of normal production work which have been designed from anatomical blueprints for specific therapeutic purposes. The ideas for appliances and adapters to suit individual patients arise from consultation between the surgeon and the engineer. These conferences are of great mutual benefit to both [illegible], who learn much about the principles and problems of each other's profession. "Retrainees" are encouraged to suggest modifications of any appliance or machine that would still further aid recovery, and some of these suggestions have evolved into standard remedial apparatus. The services of the more highly skilled men and suitable psychological cases are utilised in the design and construction of appliances required in the shop.

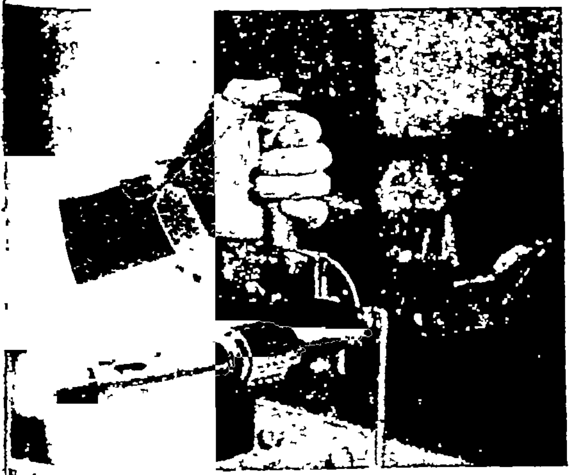

Fig. 6—Spring-loaded plunger incorporated in a hand tapping device to encourage flexion of thumb-joint after suture of tendon. Trick movements by the thumb adductors are prevented by the moulded 'Perspex' splint.

A wide selection of dry bench work which can be graded for dexterity, range of movement, and power is found invaluable in the early stages of hand and arm injuries. This work is suitable even for infections and fractures of the hand which require dressings and splints, and there are few patients who cannot thus be accommodated within a day or two of injury.

TABLE I—PERIODS OF INCAPACITY AFTER COMMON LESIONS

F.C.R. (2) B.M.A. Fracture Committee report, 1935. Cases treated in fracture clinics of Liverpool and Manchester.

Continuity of treatment and of observation is assured under these conditions up to the time for return to full work. Every aspect of the patient's welfare is covered, and his absorption back into the normal working community is made as rapidly and smoothly as possible.

Cases requiring further investigation, radiography, or plaster changes at the hospital are collected once a week and, in company with the rehabilitation superintendent, are transported to and from the hospital by coach with considerable saving of time. During these visits the superintendent can make personal contact with new patients still actually in hospital, and by means of a follow-up system the more serious cases can be assured of an early inclusion in the retraining scheme.

One of the by-products of successful rehabilitation is the number of man-hours saved to the benefit of the patient, to industry, and thus to the community as a whole. Tables I and II, give some indication of the results to be expected in some of the commoner injuries encountered in industry.

PHYSIOTHERAPY

It is obvious that physiotherapy is a necessary and important adjunct to an industrial project of this kind. Here there is a modern well-equipped unit employing a whole-time staff. It is situated close to the retraining shop, and this proximity suggests the importance attached to the close coöperation between them. From the physiotherapeutic point of view it must be admitted that the ability to rely on long periods of controlled active exercise in the shop ($42^1/_2$ hours a week) is a great advantage. On the other hand, orthodox physical treatment is found necessary in 60% of cases under the following group headings:

(1) *Re-education of Movements to a Point where they can be Utilised Actively at Work.*—In this group come, for example.

TABLE II—PERIODS OF INCAPACITY AFTER HAND INFECTIONS APRIL–DECEMBER, 1947

Diagnosis	Vauxhall patients			Other patients		
	No. of cases	Average days to no growth	Average days off work	No. of cases	Average days to no growth	Average days off work
Paronychia ..	6	7·1	3 8	42	6 6	5·5

Web-space infections	6	2 6	6·1	21	7·6	8·7

reasons were dealt with by the medical and rehabilitation departments.

PRINCIPLES

The patients or "retrainees" are paid the equivalent of their basic rates of pay plus 20% in lieu of bonus where this is applicable. Suitable work is selected from within the factory and scheduled for the shop. Much of this work is familiar to the men, and their contribution to the production demands of the factory is in our view a far more powerful stimulus to recovery than is the standard type of occupational therapy. Moreover, the advantages of working in a "live" shop where treatment is individually planned, and with a forward outlook on recovery, are of immense value, both from the economic and psychological points of view, in securing the patients' full cooperation.

One of the principles underlying the establishment of this scheme is the value of repetitive exercise, and much of the research that is going on is concerned with the adaptation of machinery so that its operation ensures controlled repetitive movement. From the point of view of the injured workman the criterion of successful treatment is his ability to do his pre-accident job. The surgeon's aim should be the maintenance or development of coordinated full muscle power across joints capable of their normal range of movement in limbs which have normal sensation. Viewed from this angle, the actual surgical procedure, reduction of fractures, suturing of tendons, and draining of felons, though essential, is merely the gateway to the path of recovery.

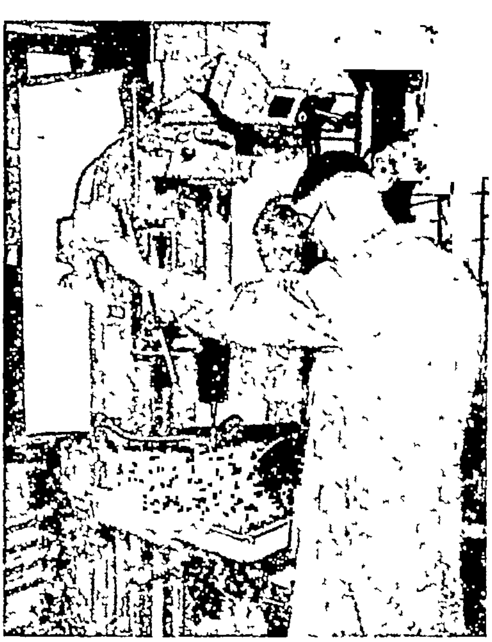

Fig. 3—Mobilisation for fractured shoulder-joint with adjustable grip transposed from right to left side of single-spindle drilling machine.

There are four causes of loss of limb function from trauma: direct severance of vital structures, tissue destruction by infection or by burning, cicatricial replacement of lost tissues or of œdematous exudates, and artificial immobilisation. In all of these the important factor militating against recovery is the time during which function is depressed or prevented, and thus the effects of all may be considered in terms of partial or total immobility. It is well recognised that there are certain therapeutic indications for rest, but these indications are far less common than has been believed in the past. This leads us to review all injuries to reduce immobilisation to the minimum and to encourage function in all structures which do not demand rest. One of the most noticeable features in a régime of this sort is the absence of circulatory disorders. An active circul is reflected in the rapid healing of bone and soft t with a consequent reduction in joint stiffness and of muscle tone. The restoration of maximum f depends on the maintenance of such muscle power movement as is possible after injury and the re-educa of such function as is lost. *It is in this proce* re-education that repetitive exercise is the key and it is just as true that practice makes perfect in accident treatment as it is in the acquisition of any skilled procedure. The development of muscle pow of range of movement, and of coordination can readily be effected by repeated attempts to what is already there.

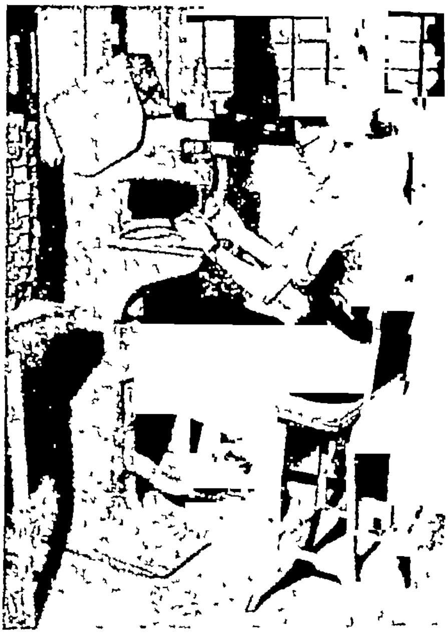

Fig. 4—Development of quadriceps by pedal-action press. This shoe riveting machine gives 10,000 movements a day and is adjus for range and power of movement at knee-joint.

This treatment requires careful control to pr fatigue; so repetitive exercise should be alternated repetitive rest. It requires control also to ensure th not only are all the normal functions being maint at a normal level *but also that re-education* is procee without the development of abnormal or "tric movements.

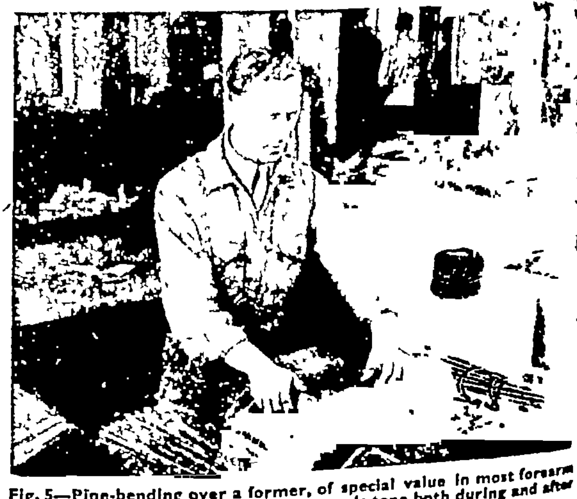

Fig. 5—Pipe-bending over a former, of special value in most forearm and hand injuries for maintaining muscle tone both during and after immobilisation in plaster.

al these cases diversional therapy, such as the construction dial appliances, was found to be most beneficial.

CONCLUSIONS

xperience leads us to believe that, where facilities vided for comprehensive rehabilitation within y, the injured employee needs little or no on to avail himself of this service. Such a has an important contribution to make towards edicine and produces good relations between the r and his employer and with the medical profession ole.

in aspects of the scheme can be expanded into a designed to deal with the accident problem of ite community.

p industrial rehabilitation centres should be on up-to-date and well-staffed hospitals where for diagnosis and controlled surgical nt are present.

hospital should be supported by an enlightened ice of general practitioners who would be prepared modify present methods of certification and accept standards regarding fitness for modified or selected k. Training in the basic principles should form t of the medical school curriculum.

ttached to the hospital there should be a remedial shop with facilities for general exercise therapy. should be closely allied with the physiotherapy rtment and should be supplied with equipment and k from the local industry.

he equipment should be of a simple nature in which principles of adaptation can be applied and studied. work done should be constructive, interesting, and ive repetitive movement.

tients treated in the workshop should be limited to who cannot be absorbed back into suitable tions in their own industry.

on with all industrial interests of the district be created by a rehabilitation superintendent from the hospital. His responsibility should led job-analysis in all accident cases and survey patients' working environment so that gradual to full employment can be expedited by a wise of interim occupation during the retraining d. He should also superintend the workshop.

h a group centre is already in existence at the Luton Dunstable Hospital, where it has been encouraging d that the support from industry has been most ous, and that the coöperation from management, vision, and the workers leaves nothing to be desired.

ACADEMIC SALARIES

soon as the Government accepted, in principle, the mendations of the third Spens Committee it e obvious that universities would have to review remuneration of doctors holding academic posts. a review might have far-reaching consequences niversity salaries as a whole, and the difficulties d are serious. On the medical side the Royal ge of Physicians, expressing grave concern, has mmended that "the remuneration of whole-time emic appointments should be brought into appro- e relationship with that of other consultants and lists," which it thinks "might be done by additional eration for hospital responsibilities." But it also s that "careful attention will be given to the uneration of academic staffs engaged in the funda- ntal sciences, so that their position will not be judiced." Its resolutions have since been endorsed y the council of the Royal College of Surgeons, in whose nal report they are now published.

Dr. Charles Hill, for the B.M.A., has pointed out that for the first time we have ranges of remuneration pted by the Government as appropriate to large ctions of the profession and we shall seek their proper application to groups not specifically covered by the two Spens reports."

Public Health

HOME NURSING OF PREMATURE BABIES

IN NEWCASTLE-ON-TYNE

F. J. W. MILLER

M.D. Durh., M.R.C.P., D.C.H.

From the City Health Department and the Department of Child Health, Royal Victoria Infirmary, Newcastle-on-Tyne

THE object of this study has been to discover the results of nursing and treating premature infants in their own homes and to collect information to answer the question whether it is better for a premature infant to be born at home and nursed there or to be admitted to hospital. The facts presented here were obtained in 1945–47 after the introduction of the notification of prematurity and the establishment of a home-nursing service for the care of premature infants. The methods used have been previously described.[1]

The background of this experience is an industrial city of 280,000 inhabitants in north-eastern England. The standards of housing have always been low but were much improved by strenuous municipal effort in the 1930's. The Overcrowding Census in 1936 showed that 10% of working-class families lived in overcrowded conditions (calculated on a basis which did not include any children under the age of one year in the permitted number for a room). Since 1939 economic standards have improved, housing conditions have deteriorated, but the infantile mortality has fallen steadily from 91 in 1937 to 40 in 1945 and 41 in 1946.

TABLE I—INCIDENCE OF PREMATURITY

Place and date	No. of births	No. of premature births	No. of live births	No. of live premature births
Newcastle-on-Tyne 1945–47 ..	16,323	1042 (*6·4*%)	15,862	916 (*5·7*%)
Birmingham [3] 1943–46 ..	85,305	5939 (*6·9*%)	83,118	5006 (*6·0*%)

In this country and in America most of the estimates of the incidence of prematurity have been made from hospital data. These vary between 3% and 12%. Baird[2] quotes Bundesen as stating the incidence of prematurity in Chicago as 6·5%. In Newcastle the incidence in 1945–47 was 6·4%, a figure almost the same as that published for Birmingham[3] (table I).

The weight distribution of the 916 infants was as expected: 54% of the premature infants were between $4^{1}/_{2}$ and $5^{1}/_{2}$ lb. at birth, 27% from $3^{1}/_{2}$ to $4^{1}/_{2}$ lb., and 19% $3^{1}/_{2}$ lb. or less.

The neonatal mortality again showed the well-known facts: of the 916 infants 208 (22·8%) died within the first twenty-eight days. Almost two-thirds of these, 124 (59·6%), died on the first day, and 188 (90·4%) in the first week.

In 1945-47 there were 400 neonatal deaths in Newcastle; 208 (52%) were in premature children.

RESULTS OF HOME NURSING

The fate of children born at home and in hospital in the first twenty-eight days is shown in table II. These groups cannot be directly compared, but the numbers and results are equal until the weight-group $4^{1}/_{2}$–$5^{1}/_{2}$ lb. is reached, where, in my opinion, the difference is likely to be the result of different obstetrical rather than pædiatric care.

many of the hand injuries, joints released from splints, sutured tendons, and rested muscles. For these the "feeling of movement" is re-educated under supervision. This is a delicate and skilled matter, and should not be entrusted to the coarser persuasion of mechanical assistance obtainable from adapted machinery.

(2) *Maintenance and Stimulation of the Circulation.*—Here the various forms of heat treatment and massage are invaluable. In the early stages of many upper-limb injuries a persistent sympathetic constrictor effect must be combated, especially in cold weather. These cases arrive at the factory in the morning with cold blue hands incapable of working efficiently. Fifteen minutes in the high-temperature wax bath releases the spasm and mobilises the limb to a point where its own activity on the production line maintains its circulation throughout the day.

(3) *Muscular Disorders.*—Muscle sprains and ruptures, fibrositis, and tenosynovitis form a large group which requires physiotherapy as a primary treatment. This is given while a patient is employed in selected or modified occupations which may or may not necessitate admission to the shop. Many of these patients are absorbed back into the factory where the demands made on them are checked by the rehabilitation superintendent so that progress is not retarded by enforcement of unsuitable work.

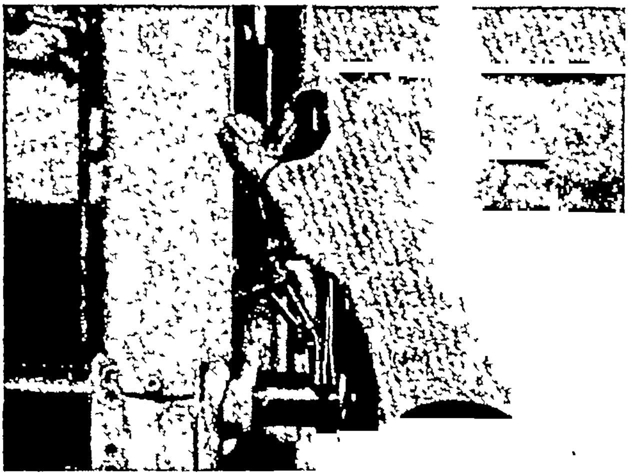

Fig. 7—Mobilisation (adduction and abduction) of thumb by grip attached to handle of drilling machine operated by squeezing action.

(4) *Infections.*—Cases of chronic sepsis, osteomyelitis, and unhealed wounds in the later stages of treatment attend for either short-wave or ultraviolet therapy.

(5) *Nerve Injuries.*—Whereas the shop can take care of non-paralysed muscles, special attention should be paid to denervated muscles to prevent wasting, contracture, and deformity. The full resources of the physiotherapeutic department are necessary to obtain maximal recovery of function.

The demand made on this department was as follows:

Therapy	*Percentage of cases treated*	*Indication*
Exercise	26·0	Early re-education of movement in tendon and joint injuries, fractures, burns; and splinted limbs.
Short-wave	18 5	Infections, tenosynovitis, and chronic osteomyelitis.
Wax baths	17·0	Healed hand injuries.
Infra-red rays	10 0	Pre-wax-heat therapy.
Faradism	9 5	Re-education of intrinsic hand muscles.
Massage	9 0	Fibrositis, tennis elbow, and scars.
Ultraviolet rays	8·5	Chronic wounds and general tonic therapy.
Galvanism	1·5	Nerve injuries.

MEDICAL REHABILITATION

Because the emphasis has been on the treatment of surgical conditions, the problem of medical rehabilitation has been thrown into greater relief. An attempt is being made to study the effects of graded work and controlled

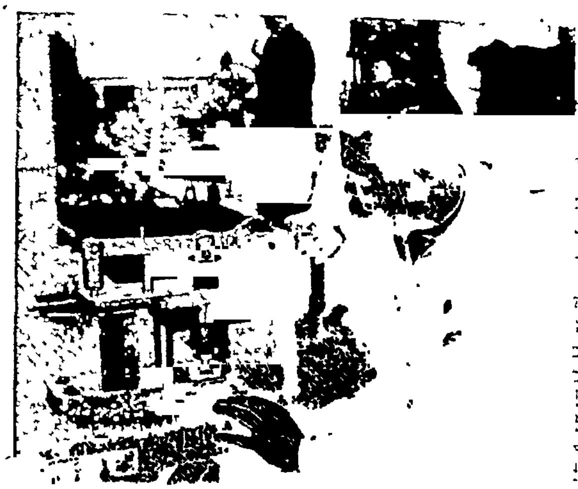

Fig. 8—Spring-loaded hand press for mobilisation of wrist in later stag of recovery from fractured scaphoid, Colles's fracture, &c.

environment on groups of medical cases which can briefly considered under the following headings:

(1) *Convalescents from acute illnesses* have responded ve well to a period of graded work before their return to f activity. Evidence of this is the fact that most of the gained in weight while in the retraining shop, but restor earning capacity after protracted illness was no doubt contributory economic factor.

(2) *Peptic-ulcer cases* remained quiescent in sympton kept good time, and required no special treatment beyo facilities for a light midday meal and relief from night wor It is not suggested that such a régime would solve the proble of the chronic dyspeptic in industry, the solution of which still far to seek.

(3) *Cases of industrial dermatitis* settled down quickly dry clean work and were submitted to trial periods in conta with the suspected cause to test their skin reactions.

(4) *Chronic medical cases,* in particular those associat with advancing age and inability to compete with young men, responded less satisfactorily, and little or no mater advantage followed attempts at rehabilitation on grade work. In our view this type of case calls for suitable permanent placement rather than for admission to a industrial rehabilitation centre.

(5) *Cases of neurosis* responded in a variable manner. Mil anxiety states with or without depression, whether precipitate by domestic or working conditions, improved provided the were of recent origin, when given a period of relief from th hectic atmosphere of the production line. Others associate with simple or chronic industrial fatigue, maladjustment, resettlement difficulties after war service responded favourabl though some required occupational adjustment on discharg

actively desire to do the work and must be volun- in the true sense of the word. They must be given well-defined responsibility and must have the support material and moral of administrative and pædiatric

The second point of great importance is the effect the home nursing on the family. Today, when so of our social services and institutions undermine confidence and strength of the family, anything in nature of common effort which increases family and solidarity becomes doubly worth while.

The effect on the morale of the family was not realised the service was started, but its significance and rtance were soon apparent. The nurse in her rôle teacher and adviser and by her personality mobilises family for duties: someone to watch at night: one to watch during the day; someone, probably neighbour, to shop; everyone interested is involved all have a sense of achievement, which gives the a good start and is far better than if he were taken to a hospital and returned a month or six weeks, an unknown infant, feared and strange.

SUMMARY

In Newcastle-on-Tyne in 1945–47 the incidence of born premature children was 5·7%: of 916 liveborn ature children 208 (22·8%) died in the first ty-eight days.

Data of the results of the home nursing of premature are presented, and it is shown that the results children of a birth weight above 3½ lb. are of the order as those which were likely to be obtained hospital.

The experiment could not have been done without the of the staff of the midwifery service of the Health Department. The assessment of the results not have been possible without the help of Dr. V. M. To all these I wish to record my appreciation and

Births and Deaths in the Third Quarter

Registrar-General[1] has issued the following for England and Wales in the quarter ended 30 (comparable figures for the same quarter last in parentheses):

births: 192,073 (216,509); rate per 1000 population (2[illegible]0) Stillbirths: 4433 (5073); rate per 1000 live still births 22·6 (22·9). Deaths: 101,664 (97,099); per 1000 population 9·4 (8·9). Deaths of infants under : 5468 (7141); rate per 1000 live births 28·0 (32·0).

The figures for stillbirths and infant mortality are lower in any previous trimester, superseding the records in the June quarter this year.

Births in the U.S.A.

Changes in the circumstances attending the birth of are noted by the United States Public Health . In 1946 over 82% of live births took place hospital; this was more than twice the percentage in . Of live births outside hospital in 1946, only were attended by a midwife or someone other than doctor, whereas the proportion in 1935 was 12·5%. 1946 infant mortality was 33·8, and maternal mortality per 1000 births; the comparable figures for 1935 55·7 and 5·8, respectively.

Encephalitis in Japan

On July 20 an epidemic of B-encephalitis broke out Japan, and by Sept. 11 a total of 6620 cases and 21 deaths had been reported. The outbreak, which has involved all prefectures but principally Tokyo, is now waning, according to W.H.O. figures. In the last week of August and the first two weeks of September the numbers of cases were 1389, 1081, and 585 respectively; and in the third week of September the daily total averaged less than 50.

In England Now

A Running Commentary by Peripatetic Correspondents

SINCE I read those articles on selection in the Students' Number I have felt like a layman who crawled into *Crockford* just by buying a clerical collar. Certainly I should never have been selected. After weeks of feelings of intense unworthiness I am now swinging over to mildly manic symptoms. What fools those fellows are in thinking that they can select! Do they know anything about most of the jobs for which they are selecting? About general practice? I do, I have done 250 locums, and I have never met two G.P.'s alike. Some get their results almost on personality alone, others on compassion, others—and probably the least effective—on pure erudition. Most mix all three in varying amounts. One man I knew succeeded by being a compendium of domestic and nursery medicine —*Nasturiorum folia* are "good for" lumbricus lothario, so-and-so is excellent for so-and-so. Another was a perfect genius at cross-examination, and even before the diagnosis must come the facts. There are 999 meanings behind "I have a pain in my stomach" and in twenty questions to get the right one requires genius.

Probably the one gift a G.P. must have or acquire is of being able to put himself in the patient's place—see with his eyes the sordid hopeless scene, hear with her ears the cry of the unborn, feel the longing behind the placid face, be in the factory where it happened, sense the closing walls of circumstance, glimpse the coloured toy that is the end of all desire, know the slow winding-sheet of toxæmia, the hope that flickers in old age and death, and the fear that has no feared thing. In short, sym-pathy with a hyphen, a subject not in the curriculum.

* * *

The first effect of the Act was to fill my surgeries to overflowing, rather to the justification of the cynics and the surprise of myself. But everyone had *something* wrong, and I have seen no evidence of malingering.

As time goes on one is able to analyse the manifold causes of this increase. First, many come who on getting a chill previously purchased a bottle of Dr. Quack's double-quick cure at the chemists, feeling now, not surprisingly, that if they pay insurance they're going to get value for it. (Very few of the public understand how little of the medical side of the scheme is paid from the insurance stamp.) Then of course—what we all expected and on the whole feel is a good thing—the mothers with children suffering from minor ailments and behaviour disturbances. What swells my prescription lists is for the mother to say, as she buttons up her child, "And while I'm here, doctor, I feel rather run down myself." But I think there is very little abuse. In fact, another reason for my swollen surgeries is that many come who should really be at home, forbearing to call me out; and my visiting-list is actually down a little on last year, saying much for the decency of human nature here, and I expect everywhere. When I am called out, it is with apologies, and I am touched by a small influx of little gifts in kind, meant to indicate the embarrassment of those who can't get used to not paying. The one thing that annoys me considerably is the number of patients coming for certificates for optical examination. Having no particular optical skill I cannot say that examination is unnecessary; and so I have to sign them all, an irritation both to me and the patient who has to wait. The sooner this certificate is abolished the better.

As to prescribing, I go my own way, as ever, avoiding polypharmacy as much as possible. But old dears with chronic and incurable varicose ulcers use up vast quantities of dressings and applications, and when an old boy with an asthma I am unable to cure tells me he has for years only had relief from "Inhalo," I feel justified in ordering it for him. As a nation we lean too much on a bottle of "Rep. Mist": but it has a psychological value, and when—an earnest and unworldly beginner—I gave good advice instead of bad drugs, my patients melted away, to reappear complaining to my senior partner. So now I give a bottle of Mist.

TABLE II—DEATHS IN FIRST 28 DAYS IN VARIOUS WEIGHT-GROUPS AT HOME AND IN HOSPITAL, 1945–47

Weight	Home group		Hospital group	
	Births	Deaths	Births	Deaths
Under 2 lb. 8 oz. ..	36	35 (97%)	33	33 (100%)
2 lb. 9 oz. to 3 lb. 8 oz.	52	32 (61·5%)	53	35 (66%)
3 lb. 9 oz. to 4 lb. 8 oz.	124	22 (17·8%)	117	23 (19·6%)
4 lb. 9 oz. to 5 lb. 8 oz.	167	14 (8·4%)	334	14 (4·2%)
All weights ..	379	103 (27·2%)	537	105 (19·5%)

Table III shows the results in home care for the first twenty-eight days. Just as a direct comparison of home and hospital births cannot be made, so it is impossible to compare directly the "specialled" and "not specialled" groups. We could not provide, during this period, special care for all premature infants born at home, and medical practitioners and district midwives called for assistance from the "premature infant" nurses at their own discretion. In general, special assistance was asked for if they thought the smallest infant might survive or the larger infant ($4^1/_2$–$5^1/_2$ lb.) gave rise to anxiety. The results, however, merit note, especially in the group of infants between $3^1/_2$ lb. and $4^1/_2$ lb., in which there were only 7 deaths among 82 infants specialled, and only 22 deaths among 124 premature infants in the whole city.

ASSESSMENT OF RESULTS

To answer in any strict mathematical sense the question whether it is better for a premature infant to be nursed at home or to be removed to hospital, it would be necessary to make a comparison between the results of the treatment of a large group of premature children born and nursed at home with the results in a group of similar composition born at home under similar conditions and admitted immediately to hospital. I do not think, however, it will ever be possible to establish these conditions but I have been helped, in forming an assessment of my results, by Dr. V. M. Crosse, of Birmingham, who has given me the results of the care of infants admitted to her premature-infant unit from home in 1944–46. The groups are very similar. I have explained that in Newcastle the special nurses tend to be called when the doctor or the midwife thinks a very small infant will have a chance of survival or when a larger infant is thought to require special attention. Dr. Crosse tells me that in Birmingham "a few infants die before admission, and naturally gross abnormalities are not admitted." Thus the groups are similar and both influenced by the same factors of selection and can be used as a basis for assessment of the home nursing. If this device is accepted as a basis of measurement, the results in the two groups can be seen to be of the same order over a birth weight of $3^1/_2$ lb. and rather less good in Newcastle below that weight. It is interesting also to compare the results from Dr. Crosse with the results of all the premature infants born and nursed home in Newcastle during these three years (table This procedure is manifestly weighting the assessm against the results of home nursing since, as I have alrea explained, some selection inevitably enters into th admitted to hospital. These results are given in tabl and show how high a standard of care can be achie at home under the most varied conditions.

TABLE III—RESULTS OF HOME CARE OF PREMATURE INFANTS FOR FIRST 28 DAYS, 1945–47

Weight	"Not specialled"			"Specialled"		
	Total	Living	Dead	Total	Living	Dead
Under 2 lb. 8 oz. ..	28	1	27	8	..	8
2 lb. 9 oz. to 3 lb. 8 oz.	27	7	20	25	13	12
3 lb. 9 oz. to 4 lb. 8 oz.	42	27	15	82	75	7
4 lb. 9 oz. to 5 lb. 8 oz.	123	109	14	44	44	..
All weights ..	220	144	76	159	132	27

DISCUSSION

Attempts to meet the problem of the care of premat infants born at home have hitherto been confined larg to the establishment of premature-infant units, and li attention has been given to the results of home care.

Though special accommodation is necessary premature infants born in hospital and perhaps for a born at home in the poorest circumstances, it is least open to question whether it would be wise or e practical to attempt to provide hospital accommodat for all premature infants born at home under a cer weight—e.g., 5 lb. It is particularly necessary answer this question now that so much thought is b given to the child-health services. My opinion is t with the expansion of the home-nursing service, impr ment in training of midwives (which should be the f tion of a few good premature-infant units in diff parts of the country), and flexible administration, mortality of premature infants could be much red by home nursing; the dangers of bringing infants hospital could thereby be avoided and, not least in th days, a more economical use made of the nursing servi

TABLE IV—FATE OF PREMATURE INFANTS ADMITTED HOSPITAL IN BIRMINGHAM COMPARED WITH FATE OF TH NURSED AT HOME BY SPECIAL MIDWIFE IN NEWCASTLE

Weight	Admission to hospital from home Birmingham 1944–46			Nursed at hom by special midw Newcastle 1945-		
	No.	Died	Survived	No.	Died	Surv
Under 2 lb. 8 oz. ..	34	30	10%	8	8	.
2 lb. 9 oz. to 3 lb. 8 oz.	117	44	63%	25	12	52
3 lb. 9 oz. to 4 lb. 8 oz.	228	30	87%	82	7	91
4 lb. 9 oz. to 5 lb. 8 oz.	200	11	95%	44	..	100

Further experience with this nursing service is obvio required both in Newcastle and in other parts of country, and I hope that the experience of others soon be recorded. In Newcastle we must give furt consideration to the problem of the premature inf under $3^1/_2$ lb. and determine in the future whether shall admit them to hospital or whether we can de other methods of home nursing which will improve results.

Finally, I wish to emphasise two important poi First, when such a service of home nursing is start the midwives or other nurses undertaking the t

TABLE V—FATE OF PREMATURE INFANTS ADMITTED HOSPITAL IN BIRMINGHAM COMPARED WITH FATE OF TH NURSED AT HOME IN NEWCASTLE

Weight	Admission to hospital from home Birmingham 1944–46			All premature infants born and nursed at home Newcastle 1945-		
	No.	Died	Survived	No.	Died	Surviv
Under 2 lb. 8 oz. ..	34	30	10%	30	35	3%
2 lb. 9 oz. to 3 lb. 8 oz.	117	44	63%	52	32	38%

marthrosis is likely after any procedure which involves ening the shoulder-joint.

1. "The difficulties in drilling the necessary holes in the noid cavity and in inserting the sutures are great." Since introduced the dental drill for this purpose, some ten years , these difficulties have been completely overcome. My regret is that I did not discover the drill until my second er (1938) was in print.

4. "Even if the torn structures are reapposed, there is iderable doubt whether they will be permanently united the formation of fibrous tissue." There is no doubt ever. When properly done, the fixation of fibrous (capsule, ligaments, or tendons) to bone is as certain anything in surgery.

"During the spasms which occur when the patient is ing round from the anæsthetic. . . ." Our patients do have postoperative convulsions or spasms, and the stion that *it is impossible to suture a muscle* (subularis) securely, because the stitches will be torn out by ular spasms, is most extraordinary.

"The coracobrachialis muscle and the short head of the ps muscle . . . by their contraction will tend to pull this ment (of coracoid process) downwards; . . ." But surely . Richardson is capable of fixing this piece of bone in place that it will not be pulled down. Elongation of the coid process is no part of my operation.

We have a safe and certain cure for recurrent dis- ation of the shoulder. It is a straightforward repair a definite and constant lesion. It does the least ible damage to the surrounding parts and it prac- lly restores the joint to its normal condition. It is difficult and it is within the competence of any geon of ordinary ability. It seems unnecessary to yet another bone-block operation to the list of tional procedures which ignore the true pathology of condition and attempt to cure the dislocation by ndabout means.

London, W.1. A. S. BLUNDELL BANKART.

BEDS FOR PULMONARY TUBERCULOSIS

—Perhaps you will allow me to reply to Dr. on's comments in your issue of Sept. 4. I cannot his suggestion that shortage of beds leads to on of motives in selecting patients for admission. , under such circumstances the case which has the est claim for admission is the one which appears to most likely to benefit by the available treatment. If resources comprise only a nursing staff, then perhaps accommodation should be used to help the chronic alid. If, on the other hand, the facilities are those of great modern thoracic hospital, surely the patient mitted should be one able to benefit most from such nities. The question of an individual or social blem should not complicate the issue.

Now, I certainly have a bias toward collapse therapy suitable cases of pulmonary tuberculosis, but I do believe in the "crash A.P.," or that quick collapse uld be the sole worthy objective in treating phthisis; equally, I should not like to feel it on my conscience a patient's health had been jeopardised by my willingness to induce a pneumoperitoneum or pneumo- rax. Few will dispute that the prognosis of the B2 B3 case of tuberculosis, conservatively treated, is —half the cases will be dead in two years. There is easing evidence that efficient collapse measures can stantially improve the outlook, and the best yardstick which to estimate initial efficacy is sputum conversion. If one aims at a programme of collapse measures for high a proportion of cases as possible, they must be gnosed and dealt with early; a delay of nine months fore admission is a substantial slice in the average onsumptive's remaining expectation of life. In this own it may be that phthisis is diagnosed early: at any ate there are less than 2000 people to each general actitioner, and over 2300 new patients were referred me in 1947, yielding 95 (4%) sputum-positive cases.

I feel confident that if Dr. Houghton's suggestions for upplementing nursing staff and absorbing waiting-lists an be realised, the results of collapse treatment generally ill be greatly improved.

Tuberculosis Dispensary, Reading. W. H. TATTERSALL
Chest Physician.

UNFORTUNATE NAMES OF HOSPITALS

SIR,—I hope that you will strongly support the suggestion by "A.B." in his letter of Oct. 16.

It was perhaps to be expected that the desirability of improvement should have occurred first to psychiatrists, but the general use today of the term "mental hospital" where other more frightening titles were in use only a few years back, shows that it is possible to make such changes. If it be objected that moneys are given or bequeathed and could not be claimed if the name were changed, I would suggest that there are ways round such a difficulty; even a private Act of Parliament should surely be possible to achieve a worth-while object like this.

That this suggestion by "A.B." is likely to appeal to you, Sir, is evident from the annotation on the Patients' Hospital in your issue of Feb. 21. Now that the need for the change has been pointed out, all those in a position to act will be glad to contribute to lightening the burden on patients and relatives of patients with "cancer," "consumption," and "incurable" maladies—a burden which it is not easy for doctors to appreciate.

Guy's Hospital, London, S.E.1. RONALD MAC KEITH.

HYALURONIDASE AND GONORRHŒAL INFECTION

SIR,—In 1929 Duran-Reynals[1] reported that the intradermal injection of testicular extract caused rapid dispersal of fluid, toxins, and particulate matter from the point of injection into the surrounding skin, and that extracts of other tissues had no such effect. This result, he suggested, was due to a change in the cells of the host brought about by some substance present in testicular extract which he termed the spreading factor. Later McClean[2] confirmed these results, and finally Chain and Duthie[3] produced evidence that the spreading factor was hyaluronidase, an enzyme which acts specifically on its substrate hyaluronic acid, which is present only in the skin, vitreous humour, and synovial fluid but absent from all other body tissues. Chain and Duthie, among others, also found that some bacterial cultures produced hyaluronidase, but they disagreed with the report of Meyer et al.[4] that hyaluronidase was present in extracts of some other tissues—e.g., ciliary body. They concluded that hyaluronidase in the body was present only in testicular extract and that bacterial contamination was responsible for the findings of Meyer et al. Finally Robertson et al.,[5] investigating cultures of various pathogens, reported that the gonococcus could not produce this enzyme.

The fact that the tissues associated with the enzyme and its substrate are the genital tract, eye, joints, and skin, which are also those affected in gonorrhœal infection, makes it difficult to believe that this association can be fortuitous. Further, the mode of invasion, the direction of spread, and the complications of gonorrhœal infection show that hyaluronidase may well play a very important part in this disease.

Invasion of the male anterior urethra by gonococci from the urethral orifice and their later extension to the posterior urethra, prostate, seminal vesicles, and epididymides is difficult to understand because (1) the gonococcus is non-motile; (2) the anterior urethra for some distance from its orifice is covered with a naturally resistant flattened epithelium, and a further barrier to proximal extension is found in the relatively resistant membranous portion; and (3) the natural direction of flow in the affected parts is distally. I suggest that the hyaluronidase in the spermatic fluid lining the urethra after coitus acts as a chemotaxic agent facilitating the spread of the infecting organisms to the non-resistant epithelium of the anterior urethra, which they penetrate, giving rise later to acute gonorrhœa. That hyaluronidase may act in this way is shown by the fact that, if two

Gent. Alk. to symbolise my presence when I'm not there.

There are two things that endanger the practice of a high standard of medicine. Firstly, a list of 4000 doesn't give one the leisure to add that bit of sympathy and wisdom that comes with spaciousness. We should be encouraged by a high capitation fee for the first thousand, and decreasing amounts for the subsequent ones. Secondly, the minor specialties. During the war I became a graded psychiatrist, and learned a lot. But if I wish to give psychiatric treatment to patients on my list, and this implies hours of patient endeavour, I must do it for seventeen bob a year, or love. Likewise circumcisions. My patients like them done when the baby is a week old and the nurse still in attendance; they don't like *going* to hospital. Well, I *do some* for the love of it, but I'm only human, and the hospital lists will soon be more swollen than ever. (Jolly good job, you may say: G.P.'s should know their place and not try to be specialists.)

If you ask whether the doctor-patient relationship has been altered I say emphatically "No." Good or bad, it's the same as before and depends on the personalities of both.

P.S.—*An irritating side issue.* Why are patients told that the chemist will provide a bottle for every prescription? Doesn't this encourage waste and thriftlessness?

* * *

These hospitable columns record from time to time the experiences of the vast band of brothers seeking appointments. Lately we were given some advice on how to supply a photograph, and the reluctant conclusion was drawn that it was better to stick to a misty representation of one's own dial than to risk all on a photo of James Mason or Greer Garson. Now a new phenomenon has come to my notice—the psychological interview.

It appears that the psychologists, still flushed with triumph after selecting many thousands of Army officers (and they did very well, for all the officers I met, however young, could read and write and some of them had charming manners), are not content with organising house parties for the Civil Service, but are lending their skill to medical selection boards. The technique of the interview is strange. No waiting about in draughty corridors suspiciously eyeing other candidates, but formal introductions all round, free cigarettes, and reassuring talk about expenses from charming secretaries. The half dozen candidates and the selection board then settle themselves round a long table for several hours' discussion. Tea arrives and more cigarettes. By this time all suspicion is lulled and there is a friendly atmosphere comparable to that in a railway compartment where the train is not more than two or three hours late and no actual discomfort has yet been suffered.

At this point the candidate must exercise extreme vigilance, for now the psychologist will tenderly inquire whether those concerned approve of this method of selection. On no account say that you cannot see any point in the whole performance and would like to know the criteria of the selection committee. Comments of this sort merely reveal to the committee unpleasant traits of obstructionism and negativism which it is your duty, as a humble person merely seeking to earn your bread and butter, to conceal. Rather, confine your remarks to vaguely phrased but enthusiastic murmurs of appreciation.

On the whole I prefer the old-fashioned board, largely composed of unknown but obviously eminent lights of the profession, who treat one with grave courtesy for twenty minutes and then appoint the chap who has already held the job for two years.

* * *

In America there is everything in the shops which we used to have before the war, plus all that has been created by advancing technology. Perhaps one might advance the thesis, though, that the principal function of the man (and even more the woman) in the street, is that of consumer; an indispensable necessity to the manufacturer, for whom the world was created. At home, of course, there still lingers the notion that the world was created for the man in the street.

Letters to the Editor

INFANTILE GASTRO-ENTERITIS AND STREPTOMYCIN

SIR,—I have read with great interest the paper Dr. James and her colleagues (Oct. 9) and last wee letter by Dr. Anderson and others.

During the 1947 epidemic of infantile gastro-enter at Aberdeen, which involved 207 cases with a fatali rate of 50·6%, an extensive study of the ætiology of t condition was carried out, the first results of which w published earlier this year.[1] Two serologically disti types of *Bacterium coli* were isolated in close associat with the disease, and one of them was identical with organism described by Bray[2] in connexion with simi cases. This particular type was recovered in 94·7 of cases, and in only 1·8% of 721 controls. B organisms were found to be highly susceptible streptomycin in vitro, being inhibited by 0·4–0·8 per ml.

Later in the year Dr. C. Gibson, of the Presbyter Hospital in New York, sent a small quantity of strep mycin which enabled us to commence clinical tri with this antibiotic. Owing to the small number cases so far treated, results are as yet inconclusive, rapid clinical improvement took place more often treated than in untreated cases in the same epidem and this clinical improvement coincided with the compl disappearance from the stools of the coliform strains question. As Dr. Anderson and others have alre stressed, nearly all gram-negative organisms tend disappear from the fæces when streptomycin is exhib by mouth, and to a lesser extent when it is gi parenterally. It is true that *Bact. coli* as well as *Prot* and paracolon bacilli reappear soon after cessation streptomycin treatment, but in our own cases suspected types of *Bact. coli* did not recur and recov was uninterrupted.

During the first half of this year, at Stoke-on-Tre I isolated the same organisms in 25 out of 32 cases gastro-enteritis, most of which were fatal. Only 2 w treated with streptomycin; both patients were extrem ill on admission, both improved dramatically on strep mycin therapy, and in both the coliforms in questi disappeared and did not recur.

I should most warmly welcome the release of strep mycin for the purposes of investigating this form treatment.

C. GILES.

Pathology Department,
Stoke City General Hospital.

RECURRENT DISLOCATION OF THE SHOULDER

SIR,—Evidently Mr. Richardson is unfamiliar with n operation for recurrent dislocation of the shoulder, f in his article of Oct. 16 he has got it wrong in almo every detail and he has created a number of difficulti which in fact do not exist.

The cause of recurrent dislocation is avulsion of t capsule with or without the glenoid ligament from t anterior margin of the glenoid cavity, and the on rational treatment is to reattach the capsule to the bo from which it has been torn. Most of the cases occ in powerful athletic young men who have anything b weak muscles. I agree that bone lesions, when presen are the result and not the cause of the dislocatio They do not affect the treatment or the prognosi Mr. Richardson says:

1. "An attempt is made to repair the capsule." This incorrect. The capsule is divided over the glenoid marg and its cut edge is fixed to the bone which has been freshene to receive it.
2. "The lesion is situated deep down in a narrow woun which easily fills with blood." Inadequate exposure an imperfect hæmostasis are, next to sepsis, the commones causes of bad surgical results. In my operation the lesion i completely exposed and readily accessible, and every bleeding point can be seen and controlled. It is not true that

GUSTAF SEVERIN.

DOSAGE OF SULPHETRONE FOR CHILDREN

SIR,—In 'Sulphetrone' treatment a blood-level of between 7 and 10 mg. per 100 ml. would seem to be desirable. The dose recommended for children under years of age given in published papers[1] and by the manufacturers is 0·5 g. daily for the first week and 1 g. daily for the second week.

Of two children under 4 years of age treated with Sulphetrone in this hospital, one, aged 2 years, weighed kg., and the other aged 3 years, weighed 11·5 kg. In these children the dosage was gradually increased till a blood-level of 7–10 mg. per 100 ml. was obtained. The first child required 6 g. and the second 3 g. of the drug daily. This dose would correspond to a dose of about 24 g. and 16 g. per day in an average adult.

Thus it would seem necessary to step up the dosage of sulphetrone in young children, in the light of blood estimations, as the optimum dose may be relatively high.

PRODUCTION OF INSULIN

SIR,—The four British manufacturers of insulin—namely, Allen & Hanburys, Boots Pure Drug Co., British Drug Houses, and Burroughs, Wellcome & Co.—are a little concerned lest the annotation in your issue of . 9 might lead to certain misleading conclusions. I should like to quote from a letter by me in the *Times* of July 23.

"... I would like to comment on the article from your Medical Correspondent entitled 'Need For More Insulin' which appeared in your issue of July 16 and which referred to the report on insulin in the April issue of the *Chronicle of the World Health Organization*. Production of insulin in this country is adequate to meet in full both home and export demands, and ample stocks are always maintained in this country. The implication in the report that the United States has only a small exportable surplus is surprising, as British manufacturers are meeting active American competition in most of the important markets of the world and are having to fight hard to maintain their own exports of insulin. Great advances have been made in the yield of insulin from pancreas as a result of the collaboration of our research teams, and there will be no relaxation of our combined efforts to achieve even better yields. The methods of collection of pancreas stated to have been recently discovered in Germany have in fact been widely known for some time; they are at best a makeshift. Immediate refrigeration of pancreas glands on removal from the animal is still a necessity if the best yields of insulin are to be obtained, and it is important that no one should get the impression that pancreas should be collected in this country other than under ideal conditions. Finally, we would emphasize that our production facilities alone could provide at least double the present quantity of insulin produced if the demand for it should arise."

There is every reason to suppose that the methods of collection being used in Germany are merely designed to ensure that pancreas is not totally wasted in slaughterhouses where adequate refrigeration facilities are not available.

Ware, Herts.

PSYCHOGENIC RHEUMATISM

SIR,—I regret that I did not have an opportunity of hearing Dr. Philip Hench's lecture on psychogenic rheumatism, annotated in your columns on Oct. 23. It would be interesting, however, to learn how many of the large number of clinicians who too commonly diagnose psychogenic rheumatism have ever taken the trouble to dissect out the spinal joints post mortem. They must be extremely few. Meanwhile, the post-mortem appearances of hysteria remain protean.

London, N.4.
I. H. MILNER.

PROPRIETARY MEDICINES UNDER THE NATIONAL HEALTH SERVICE ACT

SIR,—I am afraid Mr. Godding's reply to my letter rather obscures the issue. He has given the usual accepted definition of "ethical," but has failed to point out that there are many borderline cases. In giving the doctor carte-blanche to order proprietaries, provided he can justify the prescribing, the authorities have avoided this difficulty and shown their confidence in the doctors. Mr. Godding's article did not state that the proprietary articles ordered on N.H.I. and private prescriptions were all of the truly ethical type. The comparison N.H.I./private is now of course invalid, since the two are merged, and data collected by the *Chemist & Druggist* after July 5 over the whole country suggested that doctors were not wholly ignorant of their right to prescribe proprietary articles.

I suggest, Sir, that a lot of the research ascribed to proprietary articles is attributable to ethical proprietaries of the truest form, which we are agreed receive proper support; and that to introduce other proprietary articles needs—apart from normal business financing—no special research. No doubt there are some pages of the book left closed when claims of this sort are made. How many different compounds of aspirin and codeine are on the market under different trade names?

It is up to the authorities, when reviewing the cost of the N.H.S., to decide what future policy to adopt; and it is clear that the trade interests will make their views felt. But if Mr. Godding and other manufacturers were to stimulate, by intensive advertising, the prescribing of proprietary medicines at present they would probably prejudice their own future. Prescribing such as that cited by Mr. H. Davis, D.SC., at the National Association of Women Pharmacists' meeting on Sept. 22 is bound to have unfortunate results.

I still feel that the Chemists Federation cannot properly undertake the therapeutic assessment of proprietary medicines. In order to improve its own standing, I think the C.F. would be well-advised to drop price protection, and leave that to the Proprietary Articles Trade Association. This would at any rate mean that items on the C.F. list were accepted on merit. Also it would mean, in my view, that the C.F. would be more seriously considered by some of the eminent pharmaceutical manufacturers who do not wish to be included in the list at present.

With careful reading of my contributions to this question, I think Mr. Godding will agree that there is no real fundamental divergence of views. I shall be happy to place before him in confidence those of the C.F. articles which are, in my view, undesirable.

In closing may I say that I have just seen a publication "Bayer Products/N.H.S." May I congratulate this firm on having sufficient confidence to give this information in the form stated.

Seaham.
A. FORSTER.

COMPULSORY ADMISSION

SIR,—X.Y.'s letter of Oct. 23 is opportune. In London, the problem of gaining admission to hospital for the elderly patient exists with regard to acute as well as chronic illness. It is well known that the Emergency Bed Service often has great difficulty in finding a bed for a patient over 70, even when the only doctor who has examined him has certified that he requires urgent admission. Some hospitals are more coöperative than others, so the burden of these patients is apt to fall on the "willing horse": for example, a hospital has recently admitted, from as far as twenty miles away, a man of 72 with a strangulated hernia, a woman of 81 in coma, and a case of abortion. In each case the E.B.S. had been refused admission for these patients by 15–20 other hospitals situated nearer to the patients' homes.

Unless hospital medical staffs become more coöperative, so as to solve this problem rapidly for themselves, it will obviously be necessary for a higher authority to give a definite directive allocating the responsibility for all unwanted patients in a specified area to individual hospitals or hospital groups.

[1] Madigan, D. G. *Lancet*, July 31, p. 174.

culture tubes, one containing hyaluronidase and the other not, are placed in a medium containing organisms, the organisms tend to accumulate about the mouth of, and invade, the tube containing hyaluronidase. With the onset of acute urethritis favourable conditions exist for the infection to overcome the barrier presented by the membranous portion of the urethra, since priapism and its accompanying automatic secretion of spermatic fluid are common features of this stage of gonorrhœa. Direct spread to prostate and vesicles follows naturally, and extension to the epididymides is more satisfactorily explained on this hypothesis than by either the accidental entrance of infected urine via the vas deferens or by lymphatic spread.

The complications of gonorrhœa—iritis, rheumatism, and keratodermia—are always associated with extension of the gonococcal infection to prostate, vesicles, an epididymides, where drainage is poor owing to anatomical structure. Therefore it seems reasonable to suggest that, owing to poor drainage, hyaluronidase and organisms are absorbed into the blood-stream, act on the susceptible tissues (containing the substrate hyaluronic acid), and so bring about the known pathological changes.

Apart from gonorrhœa, there may be a wider pathological significance in hyaluronidase and its substrate, since clinical experience shows that the removal of septic foci is followed by cure in some cases of rheumatism. It would be of interest to know if the infecting organisms in these cases could produce hyaluronidase, since Robertson et al.[5] showed that some strains of pathogens—e.g., streptococci and *Cl. welchii*—produced hyaluronidase in culture, and they suggested that it might play a part in rheumatoid arthritis. The latter possibility will, I feel sure, be found to be incorrect; on the other hand, the isolation of a group within the rheumatic diseases may be shown to depend on a hyaluronidase-producing organism from a septic focus. The fact that bee venom is a traditional therapeutic agent in the treatment of rheumatism and contains hyaluronidase suggests that the results of this treatment are possibly due to the formation of an anti-hyaluronidase.

DENTURES AND ANÆSTHESIA

SIR,—As one who has been engaged in making artificial dentures for thirty-six years, and who has been interested and engaged in administering anæsthetics for dental operations, I would like to enter an emphatic protest against Dr. Parry-Price's[1] practice of leaving dentures in place during anæsthesia. Any dentist or dental mechanic of experience will agree that no denture material yet made can be guaranteed against chipping. There is surely enough risk of portions of natural teeth and fillings becoming detached, without adding to the danger with pieces of porcelain or acrylic resin (the latter, by the way, being opaque to X ray).

For some time I have noticed that either face-piece or nose-piece obstructs the breathing by its very pressure on the levator nasi muscle—an observation confirmed by anæsthetists to whom I have spoken. Consequently, I am endeavouring to devise an inhaler in the form of a metal or plastic box which would rest upon the forehead, its top end plugging directly into the large-bore tube of the anæsthetic apparatus, and having at its lower end two soft metal tubes, bent so as to enter the nostrils, each fitted with a soft rubber "stall" to ensure an air-tight fit and prevent damage. Such an inhaler would, I think, not only overcome the stifling feeling that our patients complain of, but always maintain a good airway, no matter how hollow the patient's cheeks.

Lyme Regis. ERNEST H. PHILLIPS.

SIR,—Every anæsthetist must sympathise with Dr. Parry-Price in the difficulties he mentioned in his letter last week, and he is to be congratulated on his experience of leaving full dentures in position during anæsthesia. Unfortunately not every anæsthetist is careful, and all are human, and I cannot help feeling that it is better that nurses should still be taught that all dentures should be removed before operation, than that the occasional single tooth should slip into the trachea; certainly an exception might be made in the case of th patient who strongly objects on cosmetic grounds. D G. J. Rees and I described in THE LANCET (Feb. 21) buccal support for the edentulous which we felt was adequate as, and yet safer than, a full denture.

I confess that I have more confidence in passing laryngoscope in an edentulous patient than in t presence of a full set of teeth.

CAROTID-SINUS SYNDROME

SIR,—From the point of view of clinical diagno the case described last week by Dr. Turner and Profes Learmonth is interesting: They certainly proved th this man had a hypersensitive carotid-sinus reflex, b I am not so sure that his attacks of intense verti staggering, and vomiting were due to this. These a not the symptoms usually produced by cardiac asysto and this man's spontaneous attacks never seem to ha followed the usual pattern of syncope or convulsio In my experience it is very difficult to assert that labyrinthine cause of vertigo is excluded: tinnitus a deafness may not occur till much later, and I doubt tests are decisive. Remissions of labyrinthine vert may last for months or years.

I venture to think that the diagnosis in this c remains in some doubt.

Newcastle-on-Tyne. F. J. NATTRASS

DEEPER AND DEEPER

SIR,—In your issue of Sept. 4 (p. 390) I read w interest that a British diver, Petty Officer Bolla reached a depth of 535 ft. in Loch Fyne on Aug. thereby beating the former record for deep diving set in 1945 by the young Swedish engineer and diver, A Zetterström. Mr. Bollard and the Royal Navy, wh has always contributed in such a splendid way to t development of diving, are to be congratulated on a n and extremely good achievement.

I am, however, anxious to make some comments a corrections to your note. When the dive during wh Zetterström died was made on Aug. 7, 1945, the de reached was not 480 ft. but 525 ft. (160 metre Zetterström made this descent, as he had so oft before, using a synthetic gas mixture (hydrogen wi 4% oxygen) of his own invention. He died on his w to the surface. It should, however, be emphasised th his death was not due to any inherent deficiency in t method. He attained the great depth aimed at witho difficulty, and at that time this depth, of 160 metres, w the world record for open-sea diving in a flexible divin suit. The ascent also proceeded quite normally at fir Owing to a grave mistake on board the diver's boat wire (guy) attached to the diving platform was broug home too rapidly and not in accordance with t previously calculated decompression tables. From depth of approximately 164 ft. (50 metres) the div was thus suddenly brought directly to the surfac Zetterström died from acute lack of oxygen and viole decompression sickness.

Two articles have lately been published on the Zette ström method for deep diving with hydrogen. One these is a translation of a paper written in 1945 Zetterström himself[1]; in the other Bjurstedt a Severin[2] discuss the physiological aspects of t method.

As far as I am aware, 535 ft. is still the world reco for open-sea deep diving. However, it may be pointe out that Behnke, in a report (1947) from the U.S. Nav Medical Research Institute, Bethesda, entitled "A revie of physiologic and clinical data pertaining to decom pression sickness," mentions a simulated dive to a dept of 550 ft. in a wet pressure tank in April, 194 A helium-oxygen mixture was breathed and the dive remained in good condition throughout the period of th dive and afterwards.

Your short notice does not mention the kind of g mixture breathed by Mr. Bollard. In view, however, o the narcotic effect of nitrogen and the great breathin tance. it does not seem probable that the gas used was ordinary air. Further information on this point would be very welcome.

CONVALESCENCE: FEE OR FREE?

SIR,—Since July 5 the arrangements for providing children with convalescent treatment have been changed; as the new machinery comes into use, certain defects have appeared. Before that date convalescent treatment for school-children (at least in London) was largely provided through the Invalid Children's Aid Association, though much of the actual cost was defrayed by local education authorities. The system worked reasonably well. The association accumulated a good deal of information about the convalescent homes, which enabled them to place the children in the appropriate ones, and the education authorities accepted their responsibility to pay. It was with the laudable intention of removing this burden from the rates to the national exchequer that the new procedure was set up in the National Health Service Act.

The Ministry of Health has classified the former convalescent homes into two groups: (1) "holiday homes," where medical and nursing treatment is not provided, and (2) "convalescent homes," where such treatment is provided. The second group has been taken over by the regional boards, but the first group has not. So treatment in a convalescent home is free; but when given in a holiday home somebody has to pay the bill—the parents if they can afford it, or else the education authority or a charitable fund. This puts a school medical officer in a difficult position when he has to decide which type of home to recommend for a convalescent child—either a convalescent home, maintained by national funds, or a holiday home, when his own authority may be asked to foot the bill. His inclination to plump for the former will be reinforced by two powerful arguments. First, some authorities, thinking that all convalescent treatment would be free, have made no financial provision for it after the appointed day; and secondly, it is hard to see what sort of convalescent can do without medical and nursing treatment. The sequel might have been foreseen: convalescent homes have long waiting-lists, holiday homes stand empty; and the children suffer.

Other anomalies have arisen. Some holiday homes do provide treatment for some of their patients—e.g., they may have a ward reserved for heart disease. A child sent here will have to be paid for, though exactly the same treatment in a neighbouring institution would be free. Accommodation for this type of patient is scarce, so these wards should not be closed. It is not yet clear whether regional boards will arrange all convalescent treatment centrally, or will leave hospital and local-authority welfare services to find accommodation directly with the homes. In either case, the valuable knowledge garnered by the I.C.A.A. through years of experience is likely to be lost.

I appreciate that these difficulties are the teething troubles of the new scheme, and I point them out in the belief that it is best to do so early while procedure is still fluid.

Whipps Cross Hospital, London, E.11. E. HINDEN.

*** As we remarked in an annotation on July 24 (p. 153), it is clearly contrary to the principles of the Act that some patients should have to pay for a period of recuperation in a home when others do not; and it seems an unnecessary complication that the cost of holiday homes should fall on local authorities while that of convalescent homes is met by the regional boards. Our suggestion that other hospitals should follow the lead of some teaching ones in paying the holiday-home fees for their own convalescents would still leave a large class of convalescent children unprovided for.—ED. L.

LETTER TO A NEPHEW

SIR,—The final paragraph in the original letter (pre-Nelson) proves the author so sensible of true values that it should dismiss X.Y.Z.'s fears. These arose from a few earlier phrases, directed, I think, against "narrow-minded fanaticism," rather than the following of the vocation of healing—a very practical idealism, involving a deliberate devotion to the relief and encouragement of fellow men and women in distress. Our profession, most of all that of a general practitioner, gives supreme opportunities of generous response to human need suffering. Yet the patient needs something more t his doctor's devotion: he needs his wisdom, his skill, his character of truth and honour. These are fruits toil and resolution. Thomas à Kempis says truly: " doeth much that loveth much," but immediately ad "He doeth much, that doeth a thing well."

G. R. G

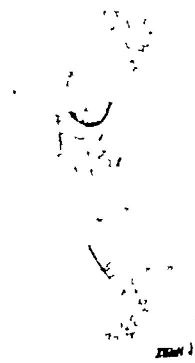
Obituary

PERCIVAL PASLEY COLE

O.B.E., M.B. BIRM., F.R.C.S., L.D.S.

Mr. P. P. Cole, whose death on Oct. 19 we announ last week, made his mark as a surgeon of wide inter who contributed particularly to plastic surgery and surgery of hernia. Much of his professional life devoted to the welfare of seamen, and two years ago was elected an honorary member of the National Un of Seamen.

Born seventy years ago at Weymouth, he received early education at Weymouth College, from which went on to Guy's Hospital. He qualified as a dental surgeon in 1899, and five years later took the Conjoint qualification. After house-appointments at his parent hospital he passed the examination to become, in 1906, F.R.C.S. Three years later he graduated as M.B. at Birmingham, where he had gone as lecturer in anatomy. He returned to London in 1910 as demonstrator of anatomy at the Middlesex Hospital; and in the two years which followed he was appointed surgeon to Queen Mary's Hospital for the East End, surgical registrar at the Royal Cancer Hospital, and assistant surgeon to the Dreadnought Hospital. The association with these three hospitals continued through his life.



During the first world war Cole turned his de training to good account in the treatment of maxil facial injuries at King George's Hospital, Waterloo Ro he also served as surgeon at the Brook War Hospit In 1919 he succeeded C. C. Choyce as dean of the Lond School of Clinical Medicine, which had been establis at Greenwich in 1910. Here he gave special thought the postgraduate training of ship's surgeons, provid for them opportunities to reside in hospital during th periods of leave. Latterly he took an important part the revision of the *Ship Captain's Medical Gui* originally composed seventy years ago by the medi superintendent of the Dreadnought Hospital Ship— forerunner of the shore hospital.

A. D. recalls that, in order to gain closer knowled of seamen's needs, Cole himself went to sea as a shi surgeon. "Out of this knowledge and experience strove constantly to enhance the status and prestige ship's surgeons, in association with Gwynne Maitl and other medical superintendents of the shipping co panies." He also campaigned for the establishment a diploma for ship's surgeons; but this scheme, wh well advanced, was interrupted by the second wor war. During the war his retirement from the Roy Cancer Hospital was deferred; he continued as surg and venereologist at the Seamen's Hospital; and h gave valuable assistance as superintendent in the E.M. In 1946 he retired from the active staff of the Roy Cancer Hospital, and in 1947 from the Dreadnough Hospital. In 1947 he was appointed O.B.E., and th year he was elected a vice-president of the Seamen Hospital Society.

"Cole's interest in surgery was broad," writes A. H. H "but there were two main channels into which h activities became directed—the filigree operation fo inguinal herniæ and plastic surgery. The former was inheritance from McGavin at the Seamen's Hospit but it was Cole's dexterity which perfected the operation, and his lucid writings on the subject which brought it to the attention of surgeons and kept it in focus during a phase of surgical development in which the use of non-absorbable suture material was at a discount. His valuable work on plastic surgery is recorded in various articles on war wounds and injuries, the reparative surgery of the upper limb, and the surgery of the jaw and face. He blended this knowledge and skill in plastic surgery with an intimate understanding of the pathology and treatment of malignant disease. 'Cancer is indivisible,' was a favourite dictum, and he was a persistent advocate of team-work. His opinion, planned treatment, and operative skill in cancer of the face, scalp, and mouth was of great value in an institution such as the Royal Cancer Hospital where he continued with this work up to a short time before his death. His last contribution to the literature, published three months ago, concerned such a case. At the age of 70 he still possessed an active mind filled with original ideas based on sound and logical principles.

"His forthright statements and unwavering principles caused him to be respected by all who worked with him. His fearless, honest, and single-minded approach to all difficulties sometimes made his passage through life bulent, but his sense of justice and tolerance won for a lasting admiration and affection."

He is survived by the son and daughter of his first riage, and by his second wife, Dr. M. P. C. Greene. memorial service is to be held at the Royal Cancer pital this Saturday, Oct. 30, at 11 A.M.

HENRY SMITH

C.I.E., M.D. R.U.I.

the early years of this century many ophthalmo-ts visited India to study Henry Smith's work at his pital at Jullundur on the surgery of cataract extrac-, and in his monograph published in India in 1910 t.-Colonel Smith described his operation for intra-lar extraction of the crystalline lens. After his ment he published a revised edition in 1928 which t the improvements he had devised on this original ique.

Colonel Smith was born in Clogher, co. Tyrone, in , and was educated at Queen's College, Galway, and Royal University of Ireland, where he graduated in dicine in 1888. Two years later he joined the Indian dical Service, and he served in the Punjab until his tirement.

In the 1914–18 war he was appointed consulting ophthalmologist in Mesopotamia, and in 1921 he returned to England and settled in Sidcup, where he continued to write and practise. Accompanied by his son, Dr. Joseph Smith, he revisited India and later Dr. Barraquer in Spain. After his tour of the United States, where he won honour, affection, and many followers, he re-edited his book on cataract. With the graphic illustrations by Dr. Darrick Vail, and mathematical considerations by his son, it has become a classic. The ill health of his wife and of his son, and their need of continuous care which he undertook, led him to return to his birthplace in Northern Ireland, where he died, on Feb. 29, in his th year.

One of his American friends writes: "Colonel Smith stood six foot four, mentally, physically, and morally. Big, handsome, and impressive, he possessed a wise sense of humour, a combative versatility, and a pair of hands that were well-nigh perfect surgical instruments. As a practical anatomist he was convincingly logical, and his sensitiveness to tissue response was uncanny. These characteristics led him to find in his general surgery the conclusive argument for intracapsular rather than extracapsular extraction of the lens, and, with the utilisation of enormous material, to conquer both difficulty and opposition. He maintained that accidental and traumatic expulsion of the lens in capsule had, willy-nilly, demonstrated that here as elsewhere, complete removal of diseased or useless tissue, where possible, is correct surgery. He sought and perfected a definite technique, and dismissed the objections of difficulty and danger as fear and insufficient skill which time and practice would banish. . . . His lifelong battle began on the plains of India. This appreciation is born in the new world. East and West pay tribute."

Colonel Smith married Miss H. D. Russell and they had two sons.

THE LATE DR. WESTERN

G. T. Western (known as "Daddy" or "Father" by his friends of both sexes) was a remarkable character. At the London Hospital this was known only to his intimate friends; the life of a bacteriologist at the medical school of a big teaching hospital is apt to be rather impersonal. But all his splendid qualities came into play at St. Hugh's, the Military Hospital for Head Injuries, to which he came from retirement in 1940 as a lieutenant aged 63. He became an institution, a man of whom many stories are still told by men who were at St. Hugh's. Everything that he undertook was done with an unusual degree of competence. Although much of his life was spent in London he was a man of the country, a craftsman steeped in country lore, which he had matched with his practical knowledge of science and his sense of business. He understood the ways of bees, how to keep oatmeal, where to buy the best saws, how to fell trees, how to store apples, how to keep the badgers from his hens, how to draw blood from the smallest veins, and so on. His standards never deviated.

At St. Hugh's he ran his laboratory easily, conserving its staff from threats of posting with a morose and almost savage effectiveness. He found time for many other things: he ran the Officers' Mess with supreme efficiency, grew vegetables on its lawn, chopped its wood, and tended bees for the Mess and for various Oxford matrons. At this stage of his life, though he was still a highly competent bacteriologist, bees interested him more than bacteria. He did the Mess shopping in a way that gained the respect if not the approval of Oxford tradesmen. Said one lady to a local shopkeeper, "Do you know Major Western, the bee expert?" "B— expert," said the shopkeeper ruefully, "Yes, that's just about what he is!" He established a record for low cost-of-living in Officers' Messes and imposed his rigorous way of life—open windows, meagre fires, no black market, no second helpings—with unbending firmness upon a highly individualistic group of neurologists. To everyone he was at times intimidating, with a short and very direct comment followed by a prolonged and penetrating, reproachful stare over the top of his spectacles. Severe reprimands to all, regardless of rank, endeared him to junior officers. All knew that his bark was worse than his bite, that he was the kindest, fairest, most unselfish, and most generous of men, ungrudging in his service to them and to the hospital. This spartan life was part of his war against Hitler. He was an unbreakable rock, as could be felt by all in the bad days of 1940, and again when he had news that his son's cruiser had been sunk, followed, after a weekend of darkness, by a cable that all was well. By his qualities and his work he contributed greatly to the success of the hospital. All at St. Hugh's would hope that in his Heaven there is a garden with woodlands and fruit trees, well-stocked beehives, a capacious tool-shed, and some fellow enthusiasts not as expert as himself.

H. C.

Appointments

LYONS, JOSEPH, M.B. Leeds, D.P.H.: M.O.H. and divisional M.D., West Riding, Yorks.

Colonial Service:

CACHIA, C., M.D., B.SC.: M.O., Kenya.
DOUGLAS, E. S. M., L.R.C.P.E.: acting M.O., Jamaica.
EGWUATU, S. O., M.B. N.U.I.: M.O., Nigeria.
LAVOIPIERRE, J. A. R., M.D. Paris, D.T.M., D.P.H.: deputy director of medical services, Mauritius.
LAYCOCK, H. T., M.A., M.B. Camb., F.R.C.S.: M.O. (surgical), British Somaliland.
O'MAHONEY, J. P., M.B. N.U.I.: chief M.O., Barbados.
PAGE, H. G., O.B.E., M.B. Edin., F.R.C.S., M.R.C.O.G.: surgeon specialist, Grenada, Windward Islands.
PEAT, A. A., M.B. Aberd.: director of medical services, Trinidad.
STEVENS, C. E. E., M.B. Belf., F.R.C.S.E.: superintendent, Cunningham Hospital, St. Christopher-Nevis.
STOBBS, J. E., M.B. Durh.: M.O., Nigeria.
STRISIVER, E. V., M.D. Berlin: M.O., special grade, Sierra Leone.
TOMLINSON, C. H., M.B. Edin.: radiologist, medical department, Jamaica.

Notes and News

TRAINING GRANTS FOR ASSISTANTS

THE Minister of Health has now notified executive councils of the terms under which practitioners may engage assistants for training under a system of Government grants; and he has suggested that principals should be invited to submit applications to take part in the scheme. The conditions are those outlined in last week's annotation (p. 656); and the announcement makes it clear that the practitioner whose application is approved will himself be responsible for appointing the assistant and for satisfying the executive council that the candidate appointed has not previously been in practice in the British Isles.

GLASGOW AND ITS ROYAL FACULTY

AT a meeting of the Scottish Society of the History of Medicine held in Glasgow on Oct. 20 with Dr. Douglas Guthrie in the chair, Prof. J. D. Mackie said that the University of Glasgow, founded in 1451, was at first modelled on French lines, but after the Reformation was reorganised by Andrew Melville. Mr. A. C. Goodall, librarian of the Royal Faculty of Physicians and Surgeons, said that the faculty was unique among medical corporations in this country in uniting surgeons with physicians. Founded in 1599 by Maister Peter Lowe it received its charter from James VI the same year. Among its many duties were the examination and licensing of all surgeons in the West of Scotland, supervision of their conduct, and ensuring the high quality of drugs. A service of free medical aid to the poor of the city was another noteworthy feature of the activities of the faculty, which next year will celebrate its 350th anniversary.

ICY CHRISTMAS

A BAD harvest nowadays is a disaster for the whole world; and the news that this year the granaries would be filled has been the one cheerful flourish in an otherwise bleak and only too convincing narrative of man's follies and misfortunes. In Labrador, where food is scarce at any time, the harvest is more elusive than elsewhere, being apt to swim off. For two summers fish have been scarce, and on land there have been few fur-bearing animals. This means a hard winter for the fisherman, hunters, and trappers, and their children. They will be hungry again, and cold. Many of their dogs, on which they depend for transport, have died, and more will die this year. The wooden hospitals and nursing stations, which have withstood forty years of arctic storms, need rebuilding; they are fuller than ever and badly need new X-ray equipment to help in the fight against tuberculosis, now on the increase.

The Grenfell Association, founded by Wilfred Grenfell to undertake medical work among British settlers in Labrador and Northern Newfoundland, has many friends on both sides of the Atlantic who like to help in its heavy and necessary task. One way to do it is to send out Grenfell Christmas cards, which are again available this year. The cards carry simple greetings only, and include several in colour: they range in price from 1*s*. 2*d*. to 6*d*. each, and there are also packets of six postcards at 2*s*. a packet, packets of six Christmas labels at 9*d*., and some pleasant purse calendars at 3*d*. each; postage is extra. They may be bought from the Secretary, Grenfell Association, 56, Victoria Street, London, S.W.1.

PREVENTION OF DEAFNESS

IN the autumn of 1946, in the town of Lund, Dr. Nils Lundgren[1] examined 1426 children in the public elementary schools and found that 15–16% were more or less deaf on one or both sides. *Nordisk Medicin*[2] points out that in the national schools in Stockholm it has long been customary to test the hearing of each child once a year. In principle, the teacher who finds that a child cannot hear whispering at a distance of less than 3 metres on one side or other must report this to a school doctor. In Stockholm provision is made for the examination of deaf children once a week, and when enlarged adenoids are found they are removed. A somewhat similar system is in operation in Göteborg, Malmö, Lund, and Norrköping, but elsewhere in Sweden early cases of deafness are largely neglected, and often the patient does not see specialist till his disability has become permanent. In th near future it is hoped that all the teeth of every Swedis child will be examined once or twice every year by a dentist and it may be asked why there is no equivalent measure fo the early detection and treatment of deafness. A child' lost teeth can to a certain extent be replaced by denture but there is no such effective substitute for good ears. D Lundgren writes: "It is just as necessary for the otolaryngologist to examine the nasopharynx, tympana, and hearing children once or twice a year in order to preserve their hearin as it is for the dentist to examine teeth at regular interv

Rh

Dr. Alexander Wiener, of New York, has circulated t various libraries bound copies of some of his contributions t the work on the rhesus factor. As he was, with Landsteine one of the original discoverers of this factor, the original pape are here reproduced; the latest reprint is from a journ dated April, 1948. Those who are studying the subje will be glad to have so much actual source material t conveniently presented. Some idea of the size of the literature that has grown up about Rh factors in a short time m be gathered from the bibliography of contributions fro Dr. Wiener and co-workers, which total 179 papers publishe with another 6 in the press. From the papers many mo key references can be gathered.

FOOD RATIONS IN GERMANY AND AUSTRIA

ACCORDING to figures issued by Economic Coöperati Administration, the normal consumer ration in the Bizo of Germany now yields about 1850 calories per day, whil the new ration for miners affords 4000 calories daily. T monthly meat ration is 300 g., compared with 100 g. la March. The over-all non-farm ration averages 2150 calori —a 15% improvement on the average a year ago. It pointed out that before the late war Germany import more than a third of her food. Moreover, it is expect that at the end of this year the combined population of t two zones will be 44 million, whereas before the war it w 34·2 million.

In Austria the normal ration was raised last month fro 1800 to 2100 calories a day. Additional food allocated workers in heavy industries has brought the average for t urban population up to 2300 calories; and in 1948–4 the average is expected to reach 2500–2600. In both countri the crops are very considerably better than last year.

THE HAVEN PRODUCTS SCHEME

THE success of a sheltered workshop turns on the goo spirit of the workers; and this derives from their sense personal achievement. Since to depend on charity alway saps morale, the best sheltered workshops are those whic are economically sound and pay a wage which owes nothin to outside benefactions. A particularly successful exampl is Haven Products,[1] opened on the Scottish Industrial Estat at Hillington, Clydeside, in 1946. The scheme was begu by doctors, social workers, and industrialists, all of who accepted the principle of community responsibility for Servic and industrial casualties. Most of the £6000 needed to sta the enterprise was subscribed by industrialists on the estat Later the project was incorporated as a private compan in which profits, instead of being distributed to shareholder go back into the workshop. The main work offered is th making of electrically heated pads and blankets; and Mess Thermega, who for many years, at Leatherhead, have bee employing ex-Servicemen with neuroses in the manufactur of this equipment, offered a subcontract on favourable terms

At Hillington the machines provided had to be speciall modified for the use of physically disabled men, benche had to be designed to allow the chair-bound worker to ge into a comfortable position, doors had to be wide enough to let invalid chairs pass easily, rest-rooms were needed, and water-closets had to be fitted with supporting rails. The place is cheerfully decorated and meals are available in a cafeteria on the ground floor.

The workshop opened in March, 1946, with two foremen, one storekeeper, and a manager. A week later 14 severel disabled men were in training, and there are now 45 at work.

1. *Nord. Med.* May 21, 1948, p. 1015.
2. *Ibid*, p. 1060.

1. Haven Products. By A. E. TURNER, T. A. STIRRAT, and Prof. T. FERGUSON, M.D. Brochure published by the Nuffield Provincial Hospitals Trust, 12 and 13 Mecklenburgh Square, London, W.C.1.

with multiple disabilities. They work an 8-hour day on days a week and earn a basic wage of 2*s.* 1½*d.* an hour plus bonuses. At present their homes are widely scattered, and they come to work by ambulance, motor chair, or public transport; but the Scottish branch of the British Red Cross is contributing funds to provide 20 houses for ex-Servicemen, through the Scottish Veterans' Garden City Association. The labour force was built up gradually as production developed.

Most of the men are severely disabled as a result of gunshot wounds of the head or spine, or such conditions as organic disease of the nervous system, heart disease, nephritis, rheumatoid arthritis, congenital muscular wasting, and amputations The average age is thirty-two, and 25 are married. In many cases an opportunity to earn a living has meant a complete change in outlook for the disabled man, from angry despair to keenness and self-confidence; and the workshop has about it an atmosphere which expresses the enthusiasm and sense of corporate life found among those employed there. As one of them wrote: "I know you'll appreciate how I feel at being able to keep the home fires burning off my own bat."

University of Oxford

On Oct. 14 the following degrees were conferred:

M.Ch.—E. G. Tuckwell.*
D.M.—E. J. E. Jones, R. G. Chambers, Zaida M. Megrah, C. Toynbee, H. A. Evans,* A. R. Wilson,* J. W. Platt,* C. Cox.*

* In absentia.

University of Cambridge

On Oct. 16 the following degrees were conferred:

M.D.—O. C. Lloyd.
M.B., *B.Chir.*—Hugh Middleton,* John Wedgwood,* N. R. [illegible],* Adrian Hill,* I. C. Peebles.*

* By proxy.

University of London

Dr. H. R. Ing, D.PHIL., will give a lecture at the London School of Hygiene, Keppel Street, W.C.1, on Friday, Dec. 3, at 5.15 P.M. He is to speak on the Pharmacology of Homologous Series.

University of Liverpool

Dr. Alexander Macdonald has been appointed to a readership in the department of bacteriology at the school of hygiene.

On Wednesday, Nov. 3, at 5 P.M., in the arts theatre of the University, Dr. Edward D. Churchill, John Homans professor of surgery at Harvard University, will deliver the William Mitchell Banks lecture. His subject is to be Wounds of the Chest—a Study of the Evolution of Method in Surgery.

University of Leeds

Dr. S. J. Hartfall has been appointed to the chair of clinical medicine in succession to Dr. Le Fleming Burrow who has retired.

Dr. Hartfall graduated M.B. at the University of Leeds in [illegible], and after holding resident appointments at the Leeds General Infirmary he became medical assistant at Guy's Hospital. In 1931 he took his B.SC. and his M.D. with distinction, and the following year he was awarded a Leverhulme research scholarship for work on anæmia and gastric secretion. In 1937 he took up the chair of therapeutics and applied pharmacology at Leeds where he also held appointments on the staffs of the General Infirmary and Public Dispensary. He holds the Territorial rank of lieut.-colonel in the R.A.M.C. His published work includes papers on the secretion of the stomach and reports on the use of gold in rheumatic diseases as practised in the Leeds Public Dispensary. In 1940 he was elected F.R.C.P.

Dr. Louise Eickhoff has been appointed senior lecturer in child psychiatry.

Institute of Laryngology and Otology

On Friday, Nov. 19, at 4.30 P.M., Mr. Walter Howarth will deliver the annual address at the institute, 330, Gray's Inn Road, London, W.C.1. The title of his lecture is to be The End of an Era—a Retrospect and a Prospect.

Medical Women's Federation

The federation has moved from its war-time quarters in Kent, and its address is now Tavistock House North, Tavistock Square, London, W.C.1 (Tel.: Euston 7765).

Royal College of Physicians of London

Dr. Robert Coope is to give the Mitchell lecture on Thursday, Nov. 18, on Tuberculous Enlargement of Intrathoracic Lymph Nodes and its Aftermath. Dr. J. A. Charles will deliver the Bradshaw lecture on Tuesday, Nov. 23. He is to speak on Victorian Medical Administrators and their Significance for Today. Both lectures will take place at 5 P.M. at the college, Pall Mall East, S.W.1.

Royal College of Surgeons of England

A meeting of fellows and members will be held at the college, Lincoln's Inn Fields, London, W.C.2, on Wednesday, Nov. 10, at 5.30 P.M. On application to the secretary, fellows and members and other diplomates of the college can obtain copies of the report from the council which will be laid before the meeting. Motions to be brought forward must be signed by the mover, or by the mover and other fellows and members, and must be received by the secretary not later than Nov. 1. A copy of the agenda will later be issued to any fellow or member who may apply for one.

On Thursday, Nov. 11, Mr. L. E. C. Norbury will deliver the Bradshaw lecture on Proctology Throughout the Ages. On Wednesday, Nov. 17, Mr. Geoffrey Keynes will give the Thomas Vicary lecture on the Portraiture of William Harvey. On Thursday, Dec. 9, Sir Reginald Watson-Jones will give the Robert Jones lecture on the Reactions of Bone to Metal. All the lectures will be held at the college, Lincoln's Inn Fields, London, W.C.2, at 5 P.M.

Faculty of Anæsthetists.—At a meeting of the board of the faculty held on Oct. 6 Mr. A. D. Marston, the dean, introduced some 19 newly elected fellows who were admitted to the fellowship by Lord Webb-Johnson, the president of the college. It was decided that whereas up to the present only holders of the diploma in anæsthetics of the two Royal Colleges should be eligible for membership of the faculty, in future, holders of the diploma of other recognised bodies should be eligible. The first Joseph Clover memorial lecture, which has been founded by the faculty, will be given by Mr. Marston on March 16, 1949.

The following have been elected to the fellowship:

H. K. Ashworth, Wesley Bourne, S. F. Durrans, H. E. Karslake Eccles, A. H. Galley, Noel Gillespie, Victor Goldman, John Halton, A. E. W. Idris, R. W. Ironside, F. Barnett Mallinson, Mrs. H. Scott Mason, Mrs. K. L. Oldham, Mrs. E. M. Taylor, Ralph M. Waters, Keith Woodruff.

University College, London

Mr. B. C. J. G. Knight, D.SC., will give three public lectures, on Biosynthesis in Micro-organisms, on Thursdays, Nov. 11, 18, and 25. Prof. C. de Duve, who holds the chair of physiological chemistry in the University of Louvain, will lecture on Dec. 6, 9, and 13 on the Control of Carbohydrate Metabolism. All the lectures will be given at 4.45 P.M. in the physiology theatre of the college, Gower Street, W.C.1.

British Association of Physical Medicine

A course in preparation for part I of the diploma in physical medicine will be held at Guy's Hospital beginning on Jan. 10, 1949, if there are enough candidates. Further information may be had from the dean of the medical school, Guy's Hospital, London, S.E.1.

Farouk I University, Alexandria

Mr. G. H. C. Ovens, F.R.C.S., has been appointed professor of clinical surgery in the university. Mr. Ovens has held the posts of clinical assistant and surgical tutor at St. Mary's Hospital, London, and of surgeon in the E.M.S.

Federation of Committees for the Moral Welfare of Children

Today, Friday, Oct. 29, at 2.30 P.M., at the Caxton Hall, S.W.1, the federation is holding a conference on Marriage in Our Time. The speaker is to be Dr. Lilias Jeffries.

Wessex Rahere Club

The first annual dinner of this club was held at the Royal Hotel, Bristol, on Oct. 17. Dr. E. R. Cullinan attended from Barts as guest of honour and some 36 members were present under the chairmanship of Dr. G. D. Kersley. Membership is open to all Barts men resident in Somerset, Wiltshire, and Gloucestershire, and the hon. secretary is Mr. A. Daunt Bateman, 3, The Circus, Bath.

Intermediate Medical Certificates for Inpatients

It has been arranged that, to relieve the pressure on hospital medical staffs, these certificates may be signed by lay officers.

Blackcurrant Syrup

The Ministry of Food has made arrangements, similar to those for last year, to provide blackcurrant syrup and purée for sale through retail chemists for children up to the age of 18, invalids, and persons in need of additional vitamin C.

Royal Statistical Society

At a meeting of the research section to be held on Tuesday, Nov. 2, at 5.15 P.M., at the E.L.M.A. Lighting Service Bureau, 2, Savoy Hill, London, W.C.2, Prof. J. B. S. Haldane, F.R.S., will open a discussion on Statistical Problems Arising in Genetics.

W.H.O. Office in South-east Asia

At a conference in New Delhi early this month, representatives of India, Ceylon, Thailand, Burma, and Afghanistan—the five countries designated to form the South-east Asia regional committee of the World Health Organisation—recommended New Delhi as the site of the regional office.

Contamination of Food by Metals

The Food Standards Committee, appointed by the Minister of Food in January, has set up a subcommittee to inquire into the metallic contamination of foods. The members include: Prof. G. R. Cameron, F.R.S., Prof. S. J. Cowell, Dr. J. M. Johnston, Dr. W. P. Kennedy, and Dr. G. Roche Lynch.

Priority for Children's Teeth

In a statement issued on Oct. 18 the British Dental Association urges the Government to provide dental treatment for children even at the expense of the rest of the population. At present the heavy demands on the general dental service—including the repair and renewal of elderly and middle-aged dentitions—make it impossible to maintain recruitment to what should be the priority service. The association further points out that school dental officers are being offered salaries below the level recommended by the Spens Committee, and adds the warning: "Unless the Ministry of Health and the Ministry of Education take a responsible and constructive interest without delay, there is the gravest danger of the existing skeleton priority dental service for our children crumbling away into dust."

The Dental Service Association further add that the shortage can only be met by using all the dental resources of the country, and suggest that "if the Denture Repair Services were brought into the scheme, much of the work which is now unnecessarily engaging the energy of dentists could be taken off their hands."

Births, Marriages, and Deaths

BIRTHS

Barras.—On Oct 1, in Malta, the wife of Dr. B. W. Barras—a son.

Bulstrode.—On Oct. 19, at Hartfield, Sussex, the wife of Dr. J. C. Bulstrode—a daughter.

Elek.—On Oct. 1, the wife of Dr. Stephen Elek—a daughter.

Garvie.—On Oct. 13, at Woking, the wife of Dr. J. M. Garvie—a son.

Lambley.—On Oct. 15, at Northampton, the wife of Mr. D. G. Lambley, F.R.C.S.—a son.

Lewin.—On Oct. 15, at Oxford, the wife of Mr. Walpole Lewin, F.R.C.S.—a daughter.

Parry.—On Oct. 21, at Cardiff, the wife of Mr. J. N. M. Parry, F.R.C.S.—a daughter.

Seward.—On Oct. 21, in London, the wife of Dr. E. C. Seward—a daughter.

Sugars.—On Sept. 29, the wife of Dr. J. C. Sugars—a daughter.

Wright.—On Oct. 18, in London, the wife of Dr. E. G. Wright—a son.

MARRIAGES

Childs—Forbes.—On Oct. 16, at Frimley, John Michael Childs, M.B., to Elizabeth Sheila Forbes.

Knowlson—Wilson.—On Oct. 5, at Oxwich, Gower, George Akenhead Knowlson, M.A., to Lydia Annie Wilson, M.D.

DEATHS

Govan.—On Oct. 17, at Cockermouth, Cumberland, George Govan, M.B. Edin., aged 84.

Innes.—On Oct. 16, Edward John Innes, M.B. Lond., Flight-lieutenant, R.A.F., aged 26.

Diary of the Week

OCT. 31 TO NOV. 6

Monday, 1st

ROYAL COLLEGE OF SURGEONS, Lincoln's Inn Fields, W.C.2
3.45 P.M. Prof. F. Wood Jones, F.R.S.: Muscles of the Bo Wall.
5 P.M. Dr. Cuthbert Dukes: Surgical Pathology of Intestin Tumours.

SOCIETY OF APOTHECARIES, Black Friars Lane, E.C.4
5 P.M. Dr. Eliot Slater: Constitutional Factors in Psycholog Medicine.

INSTITUTE OF LARYNGOLOGY AND OTOLOGY, 330, Gray's Inn Roa W.C.2
2.30 P.M. Miss D. J. Collier: Facial Paralysis from t Otological Standpoint.

Tuesday, 2nd

ROYAL COLLEGE OF PHYSICIANS, Pall Mall East, S.W.1
5 P.M. Dr. Geoffrey Marshall: Tuberculosis of the Bronchi.

ROYAL COLLEGE OF SURGEONS
3.45 P.M. Prof. D. V. Davies: Middle Cranial Fossæ.
5 P.M. Dr. Dukes: Surgical Pathology of Intestinal Tumours.

SOCIETY OF APOTHECARIES
5 P.M. Dr. Peter Bishop: Use of Sex Hormones in Therapeuti

INSTITUTE OF DERMATOLOGY, 5, Lisle Street, W.C.2
5 P.M. Dr. I. Muende: *Histopathology of the Skin.*

CHADWICK LECTURE
2.30 P.M. (Westminster Hospital medical school, Horsefe Road, S.W.1.) Dr. W. E. B. Lloyd: Prevention Tuberculosis with Special Reference to Environment.

EDINBURGH POST-GRADUATE BOARD FOR MEDICINE
5 P.M. (Royal Infirmary.) Prof. J. W. McNee: Cirrhosis of t Liver.

Wednesday, 3rd

ROYAL COLLEGE OF SURGEONS
5 P.M. Prof. Ronald Hare: Staphylococci.

LONDON COUNTY MEDICAL SOCIETY
3 P.M. (Lambeth Hospital, Brook Drive, S.E.11.) Clini meeting.

UNIVERSITY OF LIVERPOOL
5 P.M. (Arts Theatre.) Prof. Edward Churchill (Harvar Wounds of the Chest—a Study of the Evolution of Meth in Surgery.

Thursday, 4th

ROYAL COLLEGE OF PHYSICIANS
5 P.M. Sir John Parkinson: Aortic Stenosis.

ROYAL COLLEGE OF SURGEONS
3.45 P.M. Prof. H. A. Harris: Nerve-supply of the Limbs.
5 P.M. Professor Hare: Staphylococci.

UNIVERSITY OF LONDON
5 P.M. (1, Wimpole Street, W.1.) Mr. G. Ewart Marti Broncho-œsophagology in Great Britain. (Semon lectu

INSTITUTE OF DERMATOLOGY
5 P.M. Dr. G. B. Mitchell-Heggs: Complications in Eczema.

INSTITUTE OF LARYNGOLOGY AND OTOLOGY
2.30 P.M. Mr. J. Angell James: Diseases of the Antrum Dental Origin.

LONDON JEWISH HOSPITAL MEDICAL SOCIETY
3 P.M. (London Jewish Hospital, Stepney Green, E.1.) Mr. H. Levy: Æsthetics of Vision. (Presidential address.)

HONYMAN GILLESPIE LECTURE

THE VOCATION OF MEDICINE *

LORD HORDER
G.C.V.O., M.D. Lond., F.R.C.P.
NSULTING PHYSICIAN TO ST. BARTHOLOMEW'S HOSPITAL, LONDON

You are, I suppose, at various stages of your medical ing. Some of you are in the preclinical stage. Some in the wards and post-mortem room. Some are in special departments. And some of you have, no t—I won't say finished your training, because in icine, as in life, one never finishes one's training—a of you are what the law euphemistically calls ualified."

What I say today applies chiefly to those who are the beginning of their training and will later be aged in doctoring, whether as general practitioners—ing, as I must in the public interest, that this ticular genus continues to exist—or as consultants d specialists. A few, no doubt, will drop out by the yside, changing over to industry, politics, or even one of the other "liberal" professions, finding that oring is not, after all, and speaking in the vernacular, r "cup of tea."

Many years ago, Sir James Paget analysed 1000 dical students from the point of view of what happened them. It was an interesting but rather a disappointing dy.

For two reasons Paget's analysis is not applicable ay. In the first place it is possible to break away m the straight line of doctoring at a number of points the course of training, a fact which should be borne in d when any one of you begins to doubt if you are iciently interested in your human fellow creatures to ke a good doctor. You can teach in the preclinical cts; you can take up X-ray or radium work; can be a clinical or an academic pathologist; you engage in public health.

the second place there is more thought being given an formerly as to whether you should "go in" edicine at all. The whole outlook has received a jostle. If a boy or a girl is individualist in erament, and is keen upon a spice of adventure, he e may today well hesitate. Sons and daughters octors, making, as they generally do, good doctors selves, will pause and think, as indeed their parents will. This position may, of course, adjust itself; n optimist (or is this wishful thinking in the public est?) I believe that it will. Anyway, when I am ked if there is a future for doctors I still answer Yes. ll that a man hath will he give for his skin." The chinery of doctoring isn't working very smoothly the moment, but the individual doctor cannot be ensed with, and it is for the individual doctor, with public backing, to see to it that mere machinery not handicap his best work, or, should I say, these , does not find him "frustrated."

But there is another question that I am frequently d. That is, whether a boy or a girl will *make* a good tor.

Now although I hold strongly that a good doctor, like d poet, is born and not made, I do not mean by what those parents mean who see a budding doctor their child as they watch him pulling a fly to pieces, or at the child himself means when, later on, he says, the emerging ego of youth, "I always wanted to be doctor." It is true that I have no statistical evidence to the efficiency of these two groups in actual practice, I gravely mistrust the incident, and the sentiment, indicating fitness for doctoring. I don't regard the essentials for an efficient doctor as either exceptional or dramatic. Good health is a primary requisite, and I am glad to note that here in Sheffield some assurance as to this is obtained before a student is admitted. A good general education is also essential. Some *nous*, as it is called, is very helpful and a humanist approach to other folk. Indeed, I don't find it difficult, after an interview, to answer the question with a Yes or No in the majority of cases.

But all this is too late on this occasion. You are committed—though, as I said, by no means irrevocably committed to that branch of Medicine which I regard as its most valuable branch, the form which entails a "close up" between doctor and patient.

A wise man once gave a definition of what he called successful Medicine in the words "Successful Medicine is sympathy armed with understanding." I entirely agree, and I think the definition would lose none of its truth if it ran "successful Medicine is understanding touched with sympathy." I shall assume in the beginners amongst you a modicum of cleverness and goodness—to use very homely words—that will make the journey you have embarked upon a successful one. With this basis let me tell you some things that seem to me to be useful as you proceed. And you must forgive the use of the imperative tense in which I shall speak. The privilege of being exhortative is one of the few compensations allowed to those who have arrived at that stage in their professional life when they are invited to give addresses like this.

Understanding

READING

My first effort to help you will probably be hailed with acclamation. It is to warn you against studiousness. (Yes, but you must hear me through!) It was Francis Bacon, I believe, who first uttered what is only apparently a paradox, that "to spend too much time in studies is sloth." I am quite sure, from my own personal experience, that excessive reading may be a form of laziness and I shall presently tell you why. If you spend most of your time in reading you are likely to be left, not only with no time for the more important occupations of observing and thinking, but with no mind wherewith to do these essential things.

"Knowledge is valuable according as it helps us in action"—a maxim which I commend to those who are responsible for your curriculum. Froude might well have had our science and art in his mind when he said "the knowledge which a man can use is the only real knowledge that has life and growth in it. The rest hangs like dust about the brain, or dries like raindrops on the stones." Broussais applied this to Medicine: "facts which cannot be used for healing," he said, "do not belong to the physician, they belong to the naturalist."

OBSERVATION

Then as to how you should spend most of your time: the first essential is that you must cultivate the power of observation, without which—nothing. If you say this advice is a "hardy annual" on occasions like this, I should retort that hardy annuals are the only annuals worth growing. If you ask me, observe what? My reply is, observe anything, everything, and begin to do it at once. From the moment you made the decision to be a doctor everything should have become "clinical." But observe especially men and women and children and the things connected with them, for these are to be the future life of most of you. Observe the colour of their eyes, the shape of their head, the length of their hair, the clothes they wear, the way they walk and hold themselves, how they shake hands, how they say good-morning—and a hundred other things. Do this whilst you are engaged in your preclinical studies. Train your attention to be active rather than passive, and so break up *that useless reverie in which the untrained mind* spends the greater part of its life, yes, even when it is studiously reading: "Sometimes I reads and thinks and sometimes I just reads." This reverie *can*, with discipline, be changed for an alertness, an awareness, that supplies the mind with food on which it may *ruminate*. Someone in authority has said that we only use one-third of our brain for the ordinary affairs of life. I do not know how he *arrived at this conclusion*, but speaking for myself I should regard this estimate as being too liberal.

---

* Address in opening the winter session of the medical school at Sheffield on Oct. 13. In his opening passages Lord Horder paid tribute to some of his distinguished predecessors who have addressed the school.

By the *time* you enter the wards and the outpatient rooms this habit of active attention, which is by this time becoming more and more effortless, will enable you to observe many things about your patients that do not need instruments and yet are as valuable, often more valuable, than those that do require them.

At first, and probably for some time, you will observe a lot of things that are quite useless, things that are quite dissociated. How can it be otherwise? But later it will be found that your observations tend to become systematised, purposeful, and synthetically useful. In time you will develop the power of observing things that are not obvious, you will look not only *at* things but *for* things—associated things, that together make sense, that make, in the fullest meaning of the word, a diagnosis.

In this exhortation to train yourselves to observe I am not thinking of your eyes only. Your ears, also, are important, and not only in the field of auscultation. The character of a cough, the rhythm of breathing, the lack of overtones in a voice, even on the telephone, these are observations that are full of meaning to the initiated. Then I might expand all this by reference to touch and smell. These large, but vitally important observations are all the more important nowadays when instruments of precision have become so numerous and so popular. Instruments of precision enable us to measure the degree of the defects which our trained senses tell us are present. It is this clinical acumen which should suggest to us in what directions we may most profitably employ these instruments. But you cannot achieve this facility unless you have made observation a familiar habit. Then, when you have done this, that common expression, "I became aware of," does not wait until sights and sounds are shattering your senses and hammering at the door of your consciousness; you are aware almost *un*consciously. You have developed mental antennæ.

When this faculty has arrived you will find that two other things happen. You make many observations without knowing it and your observations take on a selective character: they group themselves in terms of affinity *and you develop the faculty of distinguishing* the essentials from the non-essentials.

I believe that those people who possess what is called a "clinical sense" really owe it to *these two facts*; they make many observations of which they are unconscious, and they effect a synthesis of those observations that are causatively associated. At the same time they are able to discard those that do not possess these characters.

Herein lies the nearest explanation I can give of the mental processes involved in diagnosis. And diagnosis is, of course, the end to which all observations should tend. Diagnosis, like ripeness, is all.

But side by side with the development of this facility in observation there goes necessarily the basic facts of anatomy, of physiology and of chemistry. These form the touchstone by which we are able to recognise the morbid from the healthy. Facility in observation, combined with experience of the healthy, enables us to pick out the unusual from the usual, to note deviations

from the average. I use the word "aver
than the word "normal" because normality
which involves us in a number of more o
theoretical *considerations; the average is*
of actual experience.

RECOGNISING THE AVERAGE

My third exhortation, therefore, is to tra
to recognise the average, so that your attent
struck by any deviation from it. The devia
physiological or it may be pathological;
assumed to be pathological *unless there*
reasons to the contrary. If pathological
trivial and therefore negligible, or it may b
and therefore informative. *It should be*
be important until proved otherwise.

Let me illustrate. The height of the gr
of persons of the same age and sex varies
inches, and their weight varies within a
So that we quickly *notice that this man is*
one short, this *woman* fat and that one th
readily, however, do we notice deviation
average complexion, *nor from the average ga*
of sitting on a chair, nor of lying in bed, no
hands, nor of reaction to conversation, thoug
average, too, in all these things. *As inde*
an average in the more elaborate forms of
how else do we recognise, when we see them, t
the spinster, and the *only child*?

The value of *recognising even slight deviati*
average in these and other matters is seen
stages of a number of diseases which, but for t
might otherwise go unsuspected. To those
already have some clinical experience I need o
hypo- and hyper-thyroidism, chorea, neph
disease, general paresis, and parkinsonism.

And there is more "to it" (*if you will*
vulgarism) than this. You must observe pe
for other things than complexion—for the e
pain, physical and mental, for happiness and u
and especially for anxiety and fear. What,
the dominant emotional state, and whet
only of recent origin or has been in exist
long time.

The value of this kind of observation is i
It enables us to "check up" the things th
tell us: that agonising pain, those sleepl
those days and weeks of so little food that it
life is not extinct. Look at their faces—an
put them on the scales, and on the couch—
their faces.

After a time, if you have become sensitive to
from the average, it will sometimes be bor
you that the person with whom you *are in*
not average, but for the moment you cannot s
way. You must not pass that doubt off lightly
accept the challenge, you must revise your o
and seek to explain it, for it may prove to b
the main position.

By this kind of mental discipline you wi
a power that unthinking folks call "*unca*
isn't really uncanny; it merely means that
trained your mind but that the onlooker does
working. The prestidigitator's legerdemain
"uncanny" after years of training of his han

You have now become expert, which mean
possess a power which the layman has not go
were not the case the layman's ideas of health
as sound as the doctor's; and they aren't. Th
"looks the picture of health" may not be heal
he may be a case of *polycythæmia. And*
possessor of that "broad chest," which he d
such military fashion, may be showing us o
committal signs of emphysema.

If I have made myself clear and my premises are sound, I think you will see that mere industry, whether with books or with instruments, useful though both of these are in the acquirement of knowledge, can never supply us with the fundamental wisdom that Medicine, of all human pursuits, really demands.

So much for understanding. And now a few words about the second essential in a good doctor—*sympathy*.

Sympathy

Industry can never be a substitute for sensitivity. When you begin the study of Medicine many of you possess the power of fine appreciation and delicate discrimination. Don't try to "douse" it. Don't be ashamed of it. It is of tremendous service if transmuted through the personality of a good doctor. But it will be of even greater service if you cultivate it and discipline it, when you are face to face with your patients. How many people have need of your *spiritual* sensitivity you will not realise until you make close contact with them as doctor and patient. And many of your patients (and among these will be some of the nicest) will cover their need with a spurious brusqueness which you must not fail to put aside, gently, of course, because they are just as much ashamed of their need as some of you may be of your power to supply it.

Begin to cultivate this gift of sympathy early. Sit down on the lockers of the patients who are allotted to you and talk to them. The experience will surprise you—and it will probably surprise the patient! A good deal has been said about the doctor-patient relationship; I've said a good deal about it myself. But since it is the very soul of good doctoring its importance can never be exaggerated. One of my chief reasons for distrusting the "new look" recently given to British Medicine is its tendency to disregard the "close-up" which is so important between doctor and patient. Availability of Medicine to all the people is a good idea. I am "all for it," as the expression goes. But *what* Medicine? Seeing 85 patients in a doctor's "surgery hour"—the operative word is clearly "seeing"—not Medicine. This is one of the results of the switch-over that it is to be hoped will soon be adjusted. There are other knots to unravel. But the standard of doctoring is the thing that matters and no one can maintain it except the doctor himself.

It is easy to level down; it can be done with a stroke of the pen; it is difficult to level up, and that takes time. If it be found that the machine will not enable good work to be turned out, then the machine must be reconstructed.

Meantime, the "new look" hasn't changed my view of fundamental Medicine. I still think it is a good thing that you are committing yourselves to. You will find that Medicine presents life to you in its full range. If you are a realist like old Montaigne, you will be able to "find a ravishing kind of satisfaction in pleasing another, and in doing a just action." And if you are an idealist, then, at the risk of being thought sententious, I would like to read you part of a lecture by a great physician, Peter Mere Latham, because it traces in far better language than I can do, the history of the soul of the good doctor.

"Diseases are not abstractions; they are modes of acting, different from the natural and healthy modes—modes of disorganising, modes of suffering, and modes of dying; and there must be a living, moving, sentient body for all this. This body must be your study and your continued care. Nothing must make you shrink from it. In its weakness and infirmities, you must still value it—still stay by it—to mark its hunger and thirst, in sleeping and waking, its heat and its cold; to hear its complaints, to register its groans. And is it possible to feel an interest in all this? Indeed it is. Whence comes this interest? At first it seldom comes naturally; a mere sense of duty must engender it. Presently, the quick, curious, restless spirit of science enlivens it; and then the deliberate choice of the mind.

"When the interest of attending the sick has reached this point, there arises from it a ready discernment of disease, and a skill in the use of remedies. And the skill exalts the interest, and the interest improves the skill, until, in process of time, experience forms the consummate practitioner. But does the interest of attending the sick necessarily stop here? No. What if humanity shall warm it? Then this interest, this excitement, this intellectual pleasure is exalted into a principle, and invested with a moral motive, and passes into the heart. . . ."

Whether you push straight through and become a general practitioner, or whether you specialise, or whether you branch off at any of the points in the curriculum where the science, rather than the art, attracts you, you will not repent your main decision. I believe that you can lose your soul with less ease along this path than any other I know. You will frequently be rewarded by people's gratitude and affection on account of services you scarcely thought about when you rendered them, and some of your labours that you reckoned hardest and most worthy of applause will go unrecognised. But you have your stalwarts to stimulate you, should you lack courage, and you have their examples to light you on your way. Are you doubtful of success? "I have a key in my bosom called Promise (said Christian) that will, I am persuaded, open any lock in Doubting Castle. Then, said Hopeful, that's good luck, good brother; pluck it out of thy bosom and try."

THROMBO-ANGIITIS OBLITERANS

RESULTS OF SYMPATHECTOMY AND PROGNOSIS

J. B. Kinmonth
M.S. Lond., F.R.C.S.
CHIEF ASSISTANT, SURGICAL PROFESSORIAL UNIT,
ST. BARTHOLOMEW'S HOSPITAL, LONDON

In a recent review of cases of thrombo-angiitis obliterans treated in fourteen years it was possible to trace 77 patients in whom the diagnosis was confirmed and of whom records were complete; 8 patients could not be traced. Attention was particularly directed to the natural course of the malady over a period of years, and the effects of sympathectomy in different clinical types of the disease.

A generally acceptable definition of thrombo-angiitis obliterans, or Buerger's disease, is an obliterating disease of the arteries and veins, usually affecting segments of vessels in the extremities, and occurring almost always in young men. The cause of the vascular lesion remains unknown.

DIAGNOSIS

The main features of the disease are usually clear enough to permit of diagnosis by simple methods. The history is characteristic, and clinical examination gives clear evidence of ischæmia, particularly the loss of the arterial pulses in the limbs. Special investigations are occasionally needed to make or to confirm the diagnosis, but they are not essential in the average case. Oscillometry is a useful refinement in the detection of arterial pulsation, particularly in œdematous limbs where swelling makes it difficult to feel the pulse. Arteriography is sometimes of great help in uncertain cases but is unnecessary and unjustifiable as a routine measure. Microscopy of vessels obtained from amputated digits or limbs or by arterectomy is often valuable in diagnosis. It is important to cut sections over a sufficient length of the affected vessel, because unrepresentative portions containing consecutive thrombus, and presenting a picture of clot in the lumen of an apparently normal vessel, will cause confusion if this precaution is not taken.

Thrombosis of superficial veins occurred in 24 of the 77 cases, and in 19 patients it was the first symptom of the disease. Superficial phlebitis, or a history of it, is important in diagnosis, but microscopy of an affected vein is not usually of great value, unless the nature of the swelling is in doubt, as when short lengths of small veins are involved. These may present as tender cutaneous nodules, the nature of which is discovered by biopsy and microscopy, as in the following case.

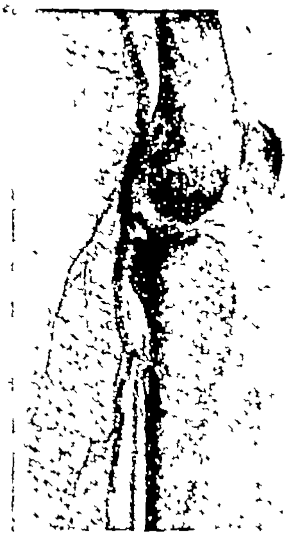

Fig. 1—Normal arteriogram of leg, showing arterial branches to calf muscles.

A man, aged 22, sustained an injury to his left knee in a car accident. Six years later the foot became cold, and he had pain in the calf after walking a few miles. The walking distance gradually diminished to 300 yards, when he sought medical aid. He was found to have a left popliteal thrombosis and no evidence of disease elsewhere. This was thought to be entirely post-traumatic, though the long interval before developing claudication was difficult to explain. Small tender cutaneous nodules next appeared spontaneously on the left leg. One of these, when removed and examined histologically, proved to be a focus of thrombophlebitis with changes usually considered typical of thrombo-angiitis obliterans.

ÆTIOLOGICAL FACTORS

An attempt was made to assess statistically the connexion between smoking and Buerger's disease. It proved impossible because the patients could not be separated into clear categories of those who stopped smoking and those who continued; too many merely reduced their smoking or continued to smoke sporadically. The one non-smoker in the series was also the only female patient. Two patients gave up smoking entirely but had fresh attacks of Buerger's disease in different parts of the body in subsequent years. Though smoking is not regarded as the cause of the disease, patients were advised to give it up because of its known vasoconstrictive effect on peripheral vessels.

This series, unlike some others, did not include an unduly high proportion of Jews.

Only 1 of the 77 patients had a positive Wassermann reaction. Syphilitic infection, when present, appears not to be of ætiological significance.

NATURAL COURSE

The average age of the patients at the onset of the disease was 35 years. The oldest patient was 48 and the youngest 16 when the disease started. The first episode in the history of this youngest patient was an isolated phlebitis several years before any arterial symptoms arose, but there were several patients whose initial manifestation was an arterial one, such as claudication starting at the age of 20 or 21.

Episodes of Activity.—It is well recognised that Buerger's disease tends to run its course in a series of episodes of activity, separated often by months or years of quiescence. Therefore all the histories were carefully analysed so that the periods between active episodes were known for every patient. The longest of these periods was fourteen years. Many other patients experienced fresh attacks of activity after an interval of ten years.

It has been suggested that Buerger's disease can burn itself out completely; but, since we know that it can manifest itself afresh after many years, it seems doubtful whether it can ever be said to be completely cured.

Duration.—There were 7 fatal cases, in whic duration of the disease and the causes of death we to be as follows:

Duration of disease at death (yr.)		*Cause of death*
5	..	Coronary thrombosis
11	..	Widespread gangrene
31	..	Widespread gangrene, including thrombosis
13	..	Mesenteric thrombosis
4	..	Buerger's disease (no more information)
2	..	Cerebral hæmorrhage
2	..	Coronary thrombosis, embolism, g
Average 9·9		

It will be seen that all the deaths were due to m tations of the disease, and that the duration disease varied widely, the longest history from o death being 31 years. One patient still alive ha 30 years since his first symptom.

CLINICAL TYPES

The cases fell naturally into three groups acc to the initial site of the disease, for it sometimes s in large vessels, sometimes in the small vessel sometimes in both simultaneously. The main cri of differentiation was the presence or absence popliteal pulse. Prognosis varied in the three gro regards alleviation of symptoms by sympathectom survival of the limb.

Obstruction of a Main Vessel.—In this group thro occurs in the femoral or in the popliteal arter popliteal pulse is not palpable, and the main sym is intermittent claudication in the calf. As a rule are pronounced postural colour changes, and w of the calf muscles is often evident. Provide thrombosis does not extend downwards into the s distal vessels, the collateral circulation is usually ade to prevent gan of the foot, the of which rem comparativ healthy.

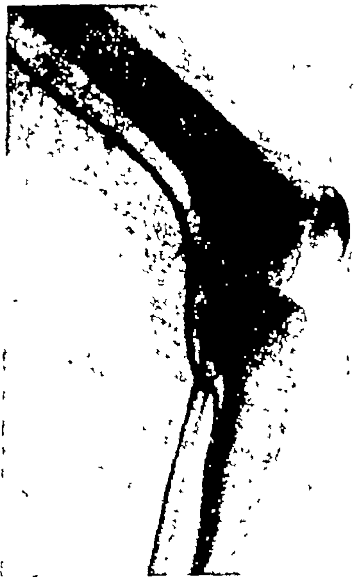

Fig. 2—Arteriogram showing Buerger's disease affecting smaller arteries to calf muscles in a patient with a palpable popliteal pulse and claudication pain in the calf.

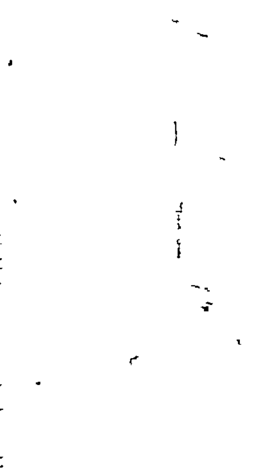
Obstruction of Vessels.—When smaller vessels a first to be atta the popliteal remains palpabl the pulses at ankle are dimi or absent. As would expect, s toms appear in foot—claudicatio the sole, rest constant erythr nosis of the skin, *coldness followe* ulceration or grene of *the* Some of the pat in this group claudication in calf, which, in presence of a popl pulse, must be a buted *to* obstruc of the muscular branches of the main vessels.

Mixed Type.—The clinical picture in this group combination of the other two, since the disease att the main and the smaller arteries simultaneously, so claudication in the calf, loss of the popliteal p t pain in the foot, with the premonitory signs of ne, all come on together.

EFFECTS OF SYMPATHECTOMY

Claudication pain in the calf is one of the prominent ptoms from which these patients may suffer. Reports of results of sympathectomy are infrequent in the otherwise extensive literature of Buerger's disease, and the statements made about its effect on claudication are often vague and unsatisfactory. Telford and Stopford[1] stated that the disability had been entirely abolished in some of the milder cases, but that the average result was persistence of claudication, often with a considerably lengthened walking distance.



—Arteriogram showing Buer- disease affecting smaller es in the foot in a patient a palpable popliteal pulse but distal pulse, and with rest pain the foot, claudication pain in the and ulcerated toes.

Others have tried to assess improvement on a percentage basis, but this may give a very misleading impression of results—in the case, for example, of a nt who could walk 15 yards before operation and yards afterwards, who would be rated as "100% rovement." In the present series a patient was not d as "improved" unless his walking distance was ed by a really useful amount after operation, a of a mile being taken as a minimum. Patients ely questioned or tested on their postoperative distance, and this was compared with the ative distance noted in the records. This often that the patients entertained a somewhat tio idea of the amount of improvement, and that and critical assessment was necessary.

dication.—The effect of sympathectomy on claudi- pain in the calf was as follows:

of disease	*No. of limbs affected*	*No. improved*
n vessels	23	9
all vessels	19	16
xed	14	0
Totals	56	25

e figures indicate that the best results are to be cted when the smaller vessels are affected—i.e., n the popliteal pulse is palpable. Improvement was observed in the mixed type.

rival of the Limb.—The fate of the limb in the three of disease for all cases in the series in which a athectomy was performed was as follows:

of disease	*Sympathectomised lower limbs* Total	*Lost*	*Preserved*
Large vessel	23	10	13
all vessels	72	17	55
xed	16	10	6
Totals	111	37	74

It will be seen that the prognosis is best when the all vessels alone are affected. Limbs classed as erved are those in which, though a minor amputation, h as that of a toe, may have been necessary, a major putation was not required.

The fate of the limb in the three types for all cases in the series, including those which were not submitted to sympathectomy, was as follows:

Type of disease	*All lower limbs* Total	*Lost*	*Preserved*
Large vessel	26	12	14
Small vessels	81	18	63
Mixed	16	10	6
Totals	123	40	83

The limbs not submitted to sympathectomy were too few to be compared with those operated on, and they also included the mildest cases. The figures for the whole series emphasise still further the better prognosis when the small vessels alone are affected.

It is clear that in the cases of obstruction of a main vessel the onset of gangrene indicates the spread of the disease to the smaller vessels—i.e., the cases have become of mixed type in spite of sympathectomy. It is impossible to say exactly what effect sympathectomy has had in stopping or slowing this process of spread, since no control series of similar untreated cases is available.

In the limbs preserved the average duration of arterial symptoms at the follow-up examination was seven years in disease of the small vessels and four years in disease of a large vessel. Only 1 limb is known to have survived with the mixed type of disease for more than two years.

Other Effects of Sympathectomy.—Besides claudication pain in the calf, other symptoms less amenable to statistical demonstration were benefited, including claudication in the sole, rest pain, and the superimposed vasospastic attacks in the extremities characterised by coldness and numbness, often resembling Raynaud's disease. It seemed also that ulcers and minor amputations healed better after sympathectomy.

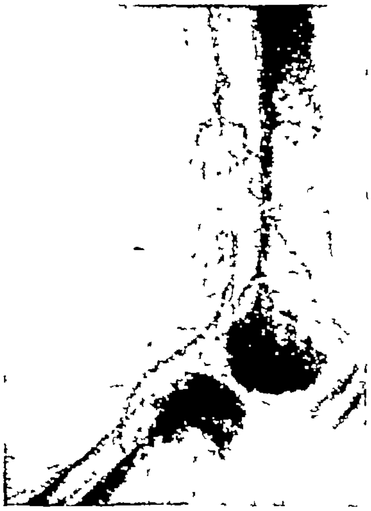


Fig. 4—Arteriogram showing Buerger's disease affecting larger arteries in a patient with impalpable popliteal pulse, claudication pain in the calf, and a relatively healthy foot.

"*Prophylactic*" *Sympathectomy.*—In some early cases of unilateral Buerger's disease bilateral sympathectomy was performed. In several of these the disease subsequently appeared in what had been the sound limb. Hence "prophylactic" sympathectomy did not give complete protection, though it possibly delayed the onset of symptoms.

SUMMARY

Buerger's disease is episodic and may recur after many years of quiescence. Without a very long follow-up, therefore, it is impossible to be certain that any particular form of treatment has cured the disease.

Cases may be divided into three groups according to the initial site of the disease in the arterial tree. The effects of sympathectomy and the prognosis for the limb are best when the smaller vessels are the first to be attacked

I wish to thank Prof. J. Paterson Ross for his great help and advice in the preparation of this paper.

OVULATION AND THE MENSTRUAL CYCLE

FRANCIS DAVIES
M.D. Lond.
PROFESSOR OF ANATOMY, UNIVERSITY OF SHEFFIELD

THERE is much divergence of opinion concerning both the time of ovulation in the menstrual cycle and the subdivision of that cycle into phases with characteristic endometrial histology. A considerable body of opinion holds that, whereas the commonest time of ovulation is about midway in the cycle (of 28 days), there is a wide range of variation in different individuals, and that even in the same individual the day of ovulation may vary in different cycles (Asdell 1927, Evans and Swezy 1931, Weinstock 1934, Burr and Musselman 1938, Stein and Cohen 1938, Seymour 1939, Altmann et al. 1941). Some investigators claim that ovulation is more closely related to the succeeding than to the preceding menstrual period (Knaus 1934, Ogino 1934, Pryde 1941, Smith 1942).

TUBAL OVA

Several workers have used tubal ova or young intra-uterine embryos to estimate the time of ovulation, and Hamilton et al. (1943) claim that the recovery of tubal ova at a definite period of the menstrual cycle gives the most reliable information concerning the time of ovulation.

The five ova found by Allen et al. (1930) indicated that ovulation took place between the 12th (or 11th) and 14th days of the cycle, although the duration of the cycles is not stated. The ovum recovered by Lewis (1931) indicated that ovulation took place 15 days before the expected onset of the next menses, assuming that the present cycle was one of 35 days, as was the preceding one, although the previous cycles were of 28 days' duration. Of two ova found by Pincus and Saunders (1937) one suggested that ovulation was 12 days before the postulated beginning of the next cycle (28-day cycles), and the other that it took place 9–13 days before the next menstruation (depending on whether the present cycle was of 26 or 30 days' duration). Miller et al. (1938) and Reimann and Miller (1939) concluded that the five ova recovered by them indicated that ovulation took place between the 15th and 17th days before the anticipated onset of the next menses (28-day cycles). Hamilton et al. (1943) discovered two ova, one of which indicated that ovulation took place 14 days before the presumed onset of the next cycle (last cycle 30 days, previously 28 days), and one that it took place 14–15 days before (28-day cycles).

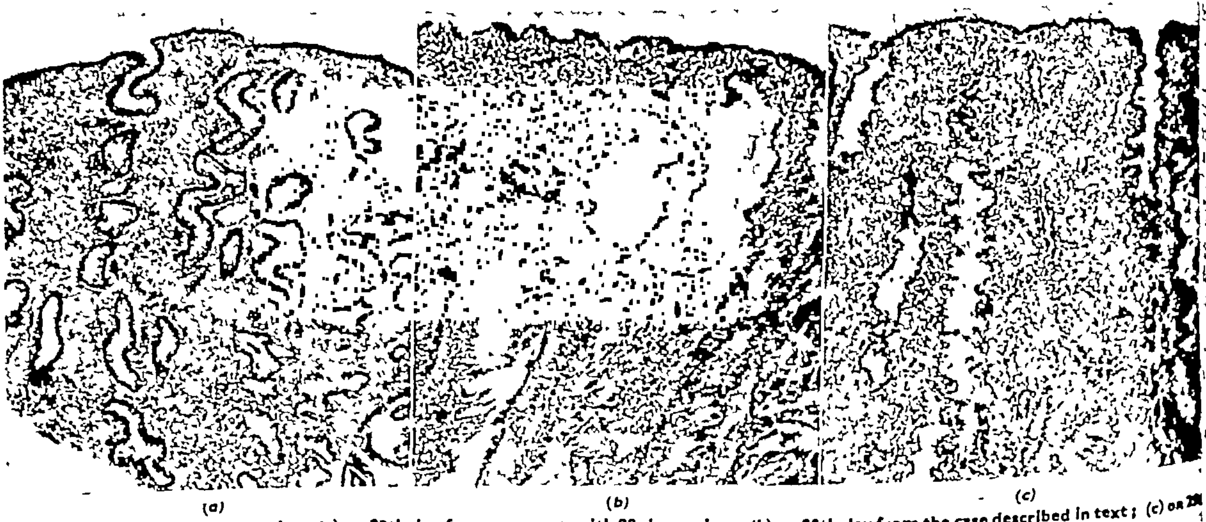
In the cases cited above the writers tacitly assume, for calculating the relation of ovulation to the onset of the next menses, that the present cycle, had it not been interrupted (generally by hysterectomy), would ha been of the same length as the immediately precedi one. There is no conclusive evidence that such assumption is warranted. Rock and Hertig (1944), fr a study of three unfertilised tubal ova and eleven you intra-uterine embryos, estimated that the interval betw ovulation and the next expected menses in these ca ranged from $11^1/_2$ to 17 days. In the case of the fertili specimens these figures were obtained by adding estimated age of each embryo to the estimated inter between operation and the next catamenia, as jud from the condition of the endometrium, although th admit that this last estimation is uncertain. When th computed the lengths of the estimated postovulat phase in terms of percentages of the estimated leng of the menstrual cycles, they found that the *average* these percentages did not deviate from that calculat by using the theoretical figure of 14 days for ovulat time, sufficiently to interfere with the indication t ovulation took place about 14 days before the onset the next expected period. But these results relate to average for the series of cases and mean neither more less than that ovulation most often took place ab 14 days before the next period but may take pl outside this limit, as is indeed revealed by the fig in their individual cases.

ENDOMETRIAL CHANGES

With regard to the changes in the structure of endometrium during the menstrual cycle, there notable differences in the results of those who h suggested the division of the cycle into various pha each of definite duration and with its particular en metrial structure (Schröder 1915, Fraenkel 1924, Sh 1925, 1941, Markee 1940, Novak 1941, Krafka 1942)

In view of existing uncertainties, some details relat to a very early human embryo described by Davies Harding (1944) are here reported, since they prov evidence that ovulation can take place early in menstrual cycle, and that the histological structure the endometrium on a particular day of the cycle influenced by the remoteness of that day from the ti of ovulation.

The embryo is in a previllous stage of development it was obtained by hysterectomy from a married wom aged 26, who had no previous abnormal gynæcologi or obstetrical history, and the embryo and the en metrium present no abnormal features. From its his logical characters, and by comparison with other p villous embryos both of man and of the macaque monk



(a) (b) (c)

Photomicrographs of endometrium (*a*) on 20th day from a woman with 28-day cycles; (*b*) on 20th day from the case described in text; (*c*) on [illegible] day from a woman with 28-day cycles. (× 50.)

was estimated to be 9–10 days old. The menstrual coital histories, obtained at the time from both and husband, were clear and definite. The woman ed that her periods came on regularly every 4 weeks ("every fourth Sunday"); this reply was accepted full knowledge that variations in the length of the in the same individual are very common. Menstrual ing took place during the first 4 days of the present ; the first coitus took place on the 10th day; took place also on each of the 11th to 15th days; uterus was removed on the 20th day. The maximum of the embryo calculated from the coital history onises with the age estimated from the histological ination, and the coitus on the 10th day was con- ed to have been the one responsible for fertilisation; this it was deduced that ovulation took place on 9th or 10th day. The relation between the coitus and ation suggests the possibility that ovulation was ced by this first act of copulation in the cycle (on 10th day). Postulation that ovulation took place in the cycle would have led to the unwarranted sion that the embryo was younger than is indicated the stage of development attained by the several yonic elements.

If ovulation took place on the 9th or 10th day, the tant corpus luteum would, by its progesterone and rogen secretion, begin to induce the secretory phase the endometrium 4 or 5 days earlier than would have the case if ovulation had occurred on the 14th day. is noteworthy that the histological structure of the metrium on the 20th day of the cycle in the present is closely similar to that of the endometrium on 24th or 25th day in several specimens examined from women with 28-day cycles, and it is certainly much advanced in the secretory phase than several specimens from women with 28-day cycles. In other cases ovulation probably took place nearer middle of the cycle. The endometrium in specimen figure) closely resembles that in *c*, and is more d in the secretory phase than that in *a*.

and Hertig (1944) estimate the interval which would expect to elapse before the onset of the next by the stage reached by the endometrium in specimens. But they admit that this estimated time ertain. In the present case the interrupted cycle l in this manner be estimated (in the absence of ancy) to terminate in 4 days—that is, the present would be deduced to be one of 24 days (in contrast the previous regular 28-day cycles), on the ground the endometrium on the 20th day has reached a comparable with that on the 24th or 25th day in imens from other women with 28-day cycles who ably ovulated near the middle of the cycle. But such duction is questionable, since there is no conclusive nce that the duration of life of the corpus luteum menstruation) is rigidly constant; and, while the tory phase will be *attained* early in the cycle if ation is early, this phase will be *maintained* so long the corpus luteum remains active; the next menses not ensue until this body ceases its activity. ough, therefore, it may be stated with reasonable ainty that in the present case ovulation took place 10 days after the onset of menstruation in a ent with hitherto regular 28-day cycles, postulation the relation of ovulation to the hypothetical next ses cannot be utilised as reliable evidence for mating the duration of the postovulatory phase of cycle.

It is concluded that, in the absence of knowledge of day of ovulation, the structure of the endometrium not accurately indicate the day of the cycle to which the endometrium belongs. Further, postulation of ulation time in a given case and deductions based on ometrial structure without knowledge of the ovulation time are concluded to be unsafe indications for use in assessing the age of young embryos.

SUMMARY

The study of a young human embryo and of the maternal menstrual history has provided evidence that ovulation can take place early in the cycle, and that the histological structure of the endometrium on a particular day of the cycle is influenced by the remoteness of that day from the time of ovulation.

Deductions concerning the relation of ovulation to the expected onset of the next menses, based on the study of tubal ova and early embryos, cannot be considered to be conclusive.

THYROIDECTOMY WITH BLOCK DISSECTION OF THE NECK FOR CARCINOMA OF THE THYROID GLAND

MARCEL DARGENT
M.D.
SURGEON, CENTRE ANTICANCÉREUX, LYONS

It is well known that carcinoma of the thyroid gland is apt to recur after partial thyroidectomy. Some patients have survived ten years, during which they have had several recurrences. To prevent such recurrences, especially the sternal, clavicular, and scapular so-called metastases, which are probably due to direct invasion along the muscles and aponeuroses, the need to resect the adjacent veins (Crile 1936) and muscles (Joll 1932, 1941) has been emphasised, and total thyroidectomy with block dissection of the neck has been advocated (Dargent and Bérard 1940, Lahey et al. 1940, Watson and Pool 1940) to ensure that all affected lymph-glands and any aberrant portions of the thyroid gland, which are particularly liable to be the seat of papillary cancer (Crile 1939), are extirpated, and to prevent metastasis through the blood-stream.

Under either local or intratracheal anæsthesia block dissection is done in several steps.

(1) A horizontal incision over the tumour meets an oblique incision along the sternomastoid muscle (fig. 1), and the two flaps are dissected and turned back. The two lobes of the thyroid gland are examined for confirmation of the diagnosis by biopsy if necessary.

I have seen three cases of nodular goitre, in patients aged over 50, which had been wrongly diagnosed as cancer. Other cases wrongly so diagnosed have included,

Fig. 2—Resection of sternomastoid muscle and external jugular vein.
Fig. 3—Resection of facial, lingual, and superior thyroid veins and superior thyroid artery.
Fig. 4—Isolation of recurrent laryngeal nerve, with dissection of its accompanying lymph-glands.

Fig. 5—Isolation of trachea and ligation of thyroid veins. If t other lobe of the thyroid gland is sound, the isthmus is divi If not, the whole of the thyroid gland is removed, and t parathyroid glands are grafted in the stump of the sternomast muscle.

in my experience, hæmatocele of the thyroid gland, and acute congestion of the thyroid gland associated with indurated cervical lymph-glands due to cancer elsewhere (nævocarcinoma of skin, mammary cancer, and cancer of larynx).

(2) The sternomastoid muscle and the external jugular vein thus exposed are divided above and below (fig. 2) and resected, and the inferior belly of the omohyoid muscle is divided to expose the internal jugular vein. If examination of the thyroid gland shows that only one lobe need be extirpated, the internal jugular vein is tied above and below and resected. If, however, total thyroidectomy is to be done, the right and left internal jugular veins are carefully isolated by dissection; and, when the ablated thyroid has been examined, the vein draining the more affected lobe is resected, the other being left.

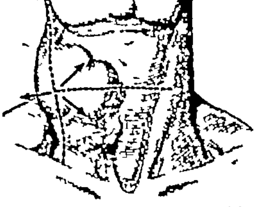

Fig. 1—Incisions for thyroidectomy and block dissection of neck.

(3) The facial and lingual veins are divided, and the superior thyroid vein on the side on which the internal jugular vein is not being resected is tied close to its junction with that vein. The superior thyroid artery can now be exposed and tied as high as possible (fig. 3). Sometimes it is difficult to free the upper pole of a carcinomatous thyroid gland from the thyroid cartilage without considerable oozing from the venules there. In securing hæmostasis care must be taken not to injure the external laryngeal nerve.

(4) After resection of the muscles lying under the thyroid the carcinomatous gland is displaced forwards, the inferior thyroid artery is divided, the recurrent laryngeal nerve is carefully isolated, and the chain of lymph-glands accompanying it is dissected away (fig. 4). Block dissection stops just short of the trachea. If one lobe of the thyroid gland is healthy, the isthmus is divided and its stump is sutured after hæmostasis (fig. 5). If total thyroidectomy is being done, the parathyroid glands are dissected away from the thyroid gland and immediately grafted into the stump of the sternomastoid muscle, and the internal jugular vein on the side of the less affected lobe is not interfered with. If necessary, the extirpation of the second lobe can be deferred to a second stage.

RESULTS

Comparatively few cases are suitable for thyroidectomy with block dissection of the neck. Since 1940 this operation has been done in only 16 of 210 cases seen at the Centre Anticancéreux at Lyons. Of the 210 patients, 34 were not fit for operation; 52 had only enough tissue removed to free the trachea; 33 were treated by radiotherapy alone; 30 underwent subtotal thyroidectomy without block dissection, including 1 who proved at operation to have simple goitre and no cance and 45 underwent extracapsular thyroidectomy witho block dissection.

Of the 16 cases submitted to thyroidectomy wi block dissection of the neck, in 2 the whole of the epithel matous thyroid gland was removed, but tetany did n develop, because the parathyroid glands were graft Within a year of operation both patients died fr metastases already present at the operation. Of t 14 patients subjected to unilateral thyroidectomy a block dissection of the neck, 1 died in hypoglycæn coma five days after the operation, and 2 patients still alive, without recurrence, three years after operati not followed by radiotherapy. Of the 11 other patien all of whom had a postoperative course of radiothera 1 has been lost sight of, 1 died of " Hodgkin's diseas four years later, and the remaining 9 survived 1–8 yea Of these, 1 already had a vertebral metastasis when was operated on, and he died of complications due paraplegia five years later. No recurrence or fre metastasis was found in any of these 9 patients.

One case was complicated by the presence of a bulk calcified carcinomatous thrombus in the internal jugul vein, making resection of the vein difficult owing to th calcareous projections which tended to tear the vein, a owing to bleeding from the thrombus. There were also sig of obliteration of the left innominate vein. The patient condition made it necessary to defer thyroidectomy to second stage. The growth in the thyroid gland proved be a Hürthle-cell carcinoma, and that in the thrombus vesicular carcinoma. The patient is still alive two yea after the operation.

RESULTS OF OTHER TREATMENTS

Freeing of Trachea.—Of the 52 patients in whol only enough tissue was removed to free the trache only 2 survived for more than five years (thanks radiotherapy.).

Radiotherapy.—Of the 33 patients submitted to radi therapy alone, 2 survived for more than five years, bu 6 developed metastases immediately after treatmen had ended.

Subtotal Thyroidectomy.—Of the 30 patients submitte to intracapsular subtotal thyroidectomy without bloc dissection of the neck 1 proved to have a simple goitr Of the 29 patients with cancer of the thyroid gland 26 were also treated by radiotherapy. Of the [illegible] survived for more than five years, but 18 had [illegible] eight postoperative recurrences.

Extracapsular Thyroidectomy.—Of the 45 patients [illegible] underwent extracapsular thyroidectomy without [illegible] dissection of the neck 28 were also treated by [illegible] therapy. Of these, 4 survived for more than five y[illegible] but 11 developed postoperative recurrences.

INDICATIONS FOR OPERATION

The decision to perform thyroidectomy with block dissection of the neck rests on the diagnosis of cancer of the thyroid gland. The best criteria are the rapidity growth of the tumour, its hardness, and paralysis of recurrent laryngeal nerve.

n a series of 131 cases confirmed histologically and including differentiated and 60 undifferentiated carcinomas the dence of these criteria was as follows: (1) 16 (28·6%) rentiated and 49 (81·7%) undifferentiated carcinomas d taken less than a year to develop; (2) 15 (26·7%) differen- ed and 51 (85%) undifferentiated carcinomas were typically d: and (3) 2 (3·5%) differentiated and 22 (36·6%) differentiated carcinomas were associated with paralysis f the recurrent laryngeal nerve.

Precedent goitre, associated thyrotoxicosis, and the ence of nodules in the neck are less characteristic cancer of the thyroid gland.

Early cancer of the thyroid gland may resemble mple goitre, in which case ordinary subtotal thyroid- tomy without block dissection of the neck will probably performed. Subsequent radiotherapy usually does t prevent recurrence. Therefore, as soon as a recurrence noted, the operation should be completed by total roidectomy with block dissection of the neck.

In the case of a rapid enlargement of the thyroid nd it is advisable to do an exploratory cervicotomy see whether or not the tumour is due to thyroiditis to struma lymphatosa, both of which simulate scirrhous rcinoma and should be treated by radiotherapy.

With a slowly growing cancer of the thyroid gland, en if metastases are already present or if the overlying n has been invaded, thyroidectomy with block dis- ction of the neck should be performed, because it will event further metastases, which otherwise are almost vitable.

PENETRATION OF CERVICAL MUCUS BY SPERMATOZOA

A METHOD OF INVESTIGATION

CLARE HARVEY *

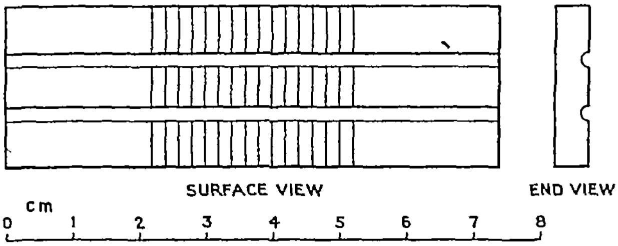
PREVIOUS methods described for investigating the y of spermatozoa into cervical mucus, such as capillary-tube method of Lamar et al. (1940) and the erslip method of Barton and Wiesner (1946), use stem in which mucus and spermatozoa are under siderable stress. The surface tension in mucus between a slide and coverslip, or in a capillary tube, t be very large relative to the energy of a progressing matozoon. Moreover, dead spermatozoa may be n across a film of mucus between slide and cover- by capillarity. Abarbanel (1946), using the capillary- method, found "grossly abnormal" spermatozoa ding cervical mucus. This suggests that here also tion is acting, for we have found fewer than 1% of orphic sperm heads in more than 10,000 spermatozoa mined in stained films of postcoital mucus; and stained films of in-vitro penetration, obtained by the method described below, support the inference that very few abnormal spermatozoa can penetrate mucus.

The present method was devised to reduce interference from surface tension. The special slide used was made to our design by W. Watson and Son Ltd. It is not unlike a Thoma counting slide with the grooves running parallel to the long axis instead of transversely, but the strip between the grooves is at the same level as the rest of the surface. The central region is marked for 3 cm. with transverse etched lines 2 mm. apart.

Mucus used for penetration tests must not contain any spermatozoa at the beginning of the test. If it is desired to test a wife's mucus against her husband's semen, the couple should be asked to avoid intercourse for 8–10 days before the mucus is extracted. All mucus should be examined for the presence of spermatozoa before it is used.



Cervical mucus slide.

METHOD

The mucus is spread over the central strip of the slide, in the region of the etched lines. It should be thin enough for the lines to show as faint shadows when the surface of the mucus is viewed with a $^2/_3$ in. objective, but thick enough not to draw away from the edges of the strip. Too thin a film should not be used.

About 0·05 ml. of semen is placed near one end of the mucus, and the drop is stroked gently with a platinum loop until the mucus is in contact with the semen for the whole width between the grooves. These grooves prevent the seepage of semen round the edges of the mucus, and maintain a standard width of surface between mucus and semen. Some semen seeps over the surface of the mucus but does not usually extend beyond 2–4 mm. It can be minimised by having a rather thick layer of mucus at the junction.

The slide is incubated at 37°C in a petri dish floored with wet filter-paper and sealed with soft paraffin. It is examined under a $^2/_3$ in. objective at any convenient intervals between 30 min. and 3 hours from the beginning of the test. No coverslip is used. In this way capillary forces are avoided except those at the fluid interface and between the mucus and the slide. Another advantage is that the test can be set up in 2 min.

For examination, the slide is placed so that the junction of semen and mucus at the end of the semen overrun is in focus, and the activity of the spermatozoa in the semen drop is noted. The slide is next moved until one of the etched lines has been crossed. (If, owing to opacity of the mucus, the lines are difficult to see, they may be located by examining the uncovered side strip of the slide.) The presence or absence of spermatozoa and their activity between this line and the next are recorded, and the slide is then moved again and the observation repeated for each 2 mm. section until no spermatozoa are found in five microscope fields in each of two adjacent sections. The search is then abandoned, and the slide can be returned to the incubator. In practice we have found that little or no increase in the distance penetrated takes place after one hour. To establish with certainty that spermatozoa are absent from the mucus beyond the last point observed with the low power, the mucus can be separated in the following way:

---

* Aided by a grant from the Medical Research Council.

A square coverslip held vertically is placed with one edge pressed firmly on the etched line 4 mm. beyond the last observed spermatozoa. The mucus beyond this is removed with the edge of a second coverslip and placed on an ordinary slide, where it can be covered and examined carefully with a $^1/_6$ in. objective.

APPLICATION

With this special slide different types of penetration can be compared by noting (1) the greatest distance reached by the spermatozoa in a given time, (2) their motility in the mucus, (3) the relative numbers of spermatozoa reaching points at various distances from the semen-mucus junction, and (4) the course of the spermatozoa within the mucus. Lack of homogeneity in the mucus can be detected by the behaviour of the spermatozoa.

The following types of penetration can be recognised, though they grade into one another:

(1) Complete failure of the spermatozoa to enter the mucus, or entry confined to a zone less than 0·2 cm. wide adjacent to the semen-mucus junction.

(2) Spermatozoa enter slowly and travel 0·5–1·5 cm. in an hour, when progress ceases. Usually few spermatozoa go further than 0·5 cm.

(3) Spermatozoa enter rapidly and after an hour's incubation are found active from the edge of the semen overrun to the farther edge of the mucus, a distance of 2·5–3·0 cm., according to the quantity of mucus used. But the numbers in the region farthest from the semen are much fewer, and the activity less, than in the first centimetre.

(4) Entry as in (3) but much more rapid, and complete. Within half an hour, or less, spermatozoa are swarming throughout the mucus.

PARKINSONISM TREATED WITH PARPANIT

W. F. DUNHAM
B.A., B.M. Oxfd, D.Phys.Med.

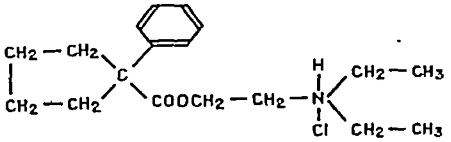
C. H. EDWARDS
M.R.C.P.

From the Neurological Research Unit, Medical Research Council, at the National Hospital, Queen Square, London

FAVOURABLE reports from Switzerland and other countries on the treatment of parkinsonism with 'Parpanit' led to the trial of this drug at the National Hospital, Queen Square.

Parpanit, a synthetic compound, was found by Grünthal (1946) to cause subjective sensory disturbances when given to healthy people. He thought that the drug might act on the proprioceptive sensory system and therefore might be of some use in the treatment of conditions characterised by muscle rigidity. After clinical trials he concluded that parpanit was of benefit in the treatment of parkinsonism. Later Hartmann (1946, 1947), in a large series of cases, confirmed Grünthal's results. Llavero, in Madrid (unpublished report), and Bickel and Dubois (1947) confirmed Hartmann's findings.

Parpanit, chemically closely related to antispasmodics such as 'Trasentin' and 'Dolantin,' has the following structure:



From the pharmacological studies of Domenjoz (194 and Heymans and De Vleeschhouwer (1947) it is cle that parpanit has atropine-like activity, but these studi do not explain why it should benefit parkinsonis (In the case of the solanaceous drugs we are similar ignorant.)

Tremor and weakness are the commonest symptom and tremor and rigidity the most striking signs, parkinsonism. The patient, or an observer, can readi appreciate any considerable change in the severity the disability, but, since tremor and rigidity va from minute to minute, objective assessment of min changes produced by treatment is difficult. We ther fore based our assessments of tremor and facility movement (under which heading are considered slowne of movement, difficulty in initiating movement, a lack of ability to perform intricate manipulations) the patients' subjective impressions, obtaining objecti confirmation, however, wherever possible. We estimat rigidity in arms and legs by a constant technique which repeated and irregularly spaced passive movemen were performed. Effects on salivation and vision well as such symptoms as giddiness and paræsthes were recorded as reported by the patient.

In all, 25 patients with parkinsonism were carefu observed. All were moderately severely affected. Po encephalitic parkinsonism and paralysis agitans w about equally represented. All the patients had b receiving solanaceous drugs in optimal doses for m than a year, and all had been under regular observati as outpatients for at least that period; 4 patients w admitted to hospital for more detailed study. T investigation was conducted in six parts. The resu obtained at each stage are described in turn. Th significance and the side-effects observed are discus subsequently.

METHOD OF ADMINISTRATION AND RESULTS

Part I

In addition to their usual solanaceous medicat 8 patients were given inert control tablets.

After a week, no change in their condition was reporte or observed.

Part II

To 19 patients, in addition to their usual solanaceo medication, parpanit was given in increasing dos until disturbing side-effects were observed.

At first, parpanit 0·0125 g. was given thrice dai after food; the morning, then the midday, then t evening doses were then increased on consecutive da by amounts not greater than half the correspondi dose for the preceding day, until unpleasant side-effec precluded further increase. Where benefit was obtaine the interval between doses was decreased and th number increased to obtain as even a level of effect possible. At this stage a decrease in the size of ea dose was sometimes necessary. Though hourly doses (many as fifteen daily) were given a trial, it was fou equally satisfactory to give the doses three-hourly four-hourly. The optimal individual doses varied fro 0·025 to 0·1 g.

On such dosage, 5 patients obtained definite subjecti improvement while taking parpanit, and a furth 4 reported slight improvement, 7 obtained no benefi and the remaining 3 felt worse. Of individual signs an symptoms, tremor was reported as reduced in 7, unaltered in 6, and as increased in 6, though observatio revealed no change in any. 10 patients noted improve facility of movement; 9 found no change. In 1 patie side-effects outweighed the improvement in othe directions, and in 4 others they were severe enough t be disturbing. The degree of benefit was never grea In only 4 was a slight improvement in gait observe es. Greater dexterity with cutlery at meals was ined by 2 patients and confirmed by their relations. In the 16 patients initially showing rigidity this was reased in 4, unaltered in 8. and increased in 2. The aining 2, feeling worse on the treatment, omitted it ore examination. In no case was the change pro- nced. Patients showing improvement have been ed for as long as thirty weeks without relapse. the 8 patients previously given control tablets rt I) 7 were included in this series. Of these, 4 were htly improved, 2 unchanged, and 1 worse.

t III

From 17 patients on optimal doses of parpanit with aceous drugs the latter were gradually withdrawn. These patients were the same as those already reported in part II, except that 2 of the 3 made worse by panit were omitted. As compared with their con- on on solanaceous drugs alone, 6 patients reported provement, 2 slight improvement, 5 no change, and terioration on parpanit. 4 found the tremor reduced, unchanged, and 6 increased. Facility of movement s stated by 7 to be increased, by 6 to be unchanged, d by 4 to be reduced. Rigidity showed an increase 1 of these patients, was unaltered in 9, and was uced in 3. 4 showed no rigidity. Further adjustment the parpanit dosage was without benefit. During ht weeks of this treatment no patient who had proved relapsed. None of these changes were pro- nced, with perhaps one exception. One man volun- ered that on parpanit he was able to dry himself after bath, which he had not previously been able to do. s increased facility of movement, however, was not ected in other activities, such as donning his overcoat walking.

t IV

Solanaceous and parpanit tablets were abruptly changed in 3 hospital inpatients.

Tablets of the two drugs, identical in appearance, given to 2 of the patients in this group. The -over of drugs passed unnoted by 1 patient; other the change in side-effects alone caused its nition. The third patient, who knew of the change medication, reported slightly improved facility of ement, but, since this persisted when a return to naceous drugs was made, this improvement must considered of doubtful significance. In none of these nts, despite careful observation by medical, nursing, physiotherapy staffs, was any objective alteration signs or behaviour noted. These 3 patients were cted for admission to hospital on economic grounds e. The dosage of both drugs was that which had viously been adjudged optimal.

t V

Inert tablets were substituted for parpanit when this being given alone in optimal dosage, the patients g unaware of the alteration (2 patients).

Previously 1 patient in this group had thought parpanit effective as the solanaceous drugs; the other had ght it more so. On the substitution of inert tablets hout the patients' knowledge, so great an exacerbation their disability was produced that they were almost pletely immobilised. (See case-record.)

t VI

Inert tablets were substituted for parpanit while full es of solanaceous drugs were also being given (2 tients).

These 2 patients, who had previously benefited mewhat from the addition of parpanit, noted slight rease in their symptoms on its substitution by inert lets. The tablets were changed in each case without knowledge of the patient. No objective change s detected.

Side-effects of Parpanit.—The tolerance to parpanit varied from patient to patient, and where benefit was obtained unpleasant side-effects began to intrude. Giddiness, a feeling of weakness, drowsiness, and paræsthesiæ developed in that order of frequency both when parpanit was given alone and when solanaceous drugs were given in addition. Hallucinosis was met with only twice, on both occasions on the combined medication. Increased blurring of vision and dryness of the mouth were complained of by 3 patients, again on combined drugs. Given alone, parpanit produced notable dryness of the mouth twice and blurring of the vision 3 times, but in both instances this was less than that produced by the usual solanaceous medication. In 6 patients hypersalivation, and in 1 rhinorrhœa, developed when the solanaceous drugs were omitted, despite the administration of parpanit. Giddiness, a sensation of weakness, and drowsiness were more common when parpanit was taken on an empty stomach, coming on usually $^1/_4$–$^1/_2$ hr. after a dose and lasting from a few minutes to about an hour. It was during the presence of these side-effects (if these were not too severe) that the maximal benefit was obtained. Throughout, careful sensory testing did not reveal any abnormality, and no changes in the tendon-reflexes were detected.

DISCUSSION

The results of this investigation have confirmed the usefulness of parpanit in parkinsonism. No striking differences in therapeutic activity were seen on replacing solanaceous drugs by parpanit, though minor changes were observed. Sometimes one drug, sometimes the other, seemed more beneficial. In contrast to this, our case-notes show that, in the absence of parpanit, the withdrawal of solanaceous drugs had previously produced a considerable recrudescence of symptoms in 8 of the 14 of our patients in whom this had been tried. As would be expected, there was a similar recrudescence of symptoms when parpanit, given alone to a patient on whom it was therapeutically active, was withdrawn. Some patients derived no benefit from either form of medication. Though as many as 15 doses have been given daily, it was found equally satisfactory to give the doses three-hourly or four-hourly. The optimal individual doses varied from 0·025 to 0·1 g.

Where parpanit was effective it was equally so whether it was added to or took the place of solanaceous drugs; when combined medication was being given, withdrawal of either produced only minor effects.

The side-effects of parpanit were similar to those of the solanaceous drugs, but their relative frequency and intensity were different. Thus, whereas giddiness, a sensation of weakness, dryness of the mouth, and blurring of vision developed with both, the first two predominated with parpanit and the last two with solanaceous medication. This is of some importance, because it is as often upon the nature of the side-effects as upon the degree of the therapeutic effects that the patient may base his choice. In this investigation side-effects were more troublesome on the combined medication.

There seem to have been no criteria by which we could have forecast the therapeutic value of either drug to any individual patient, except that, in general, those who had responded well to the solanaceous drugs responded also to parpanit.

ILLUSTRATIVE CASE-RECORD

A man, aged 68, had had tremor of the left arm for eight years. His chief complaints were unsteadiness in walking, difficulty in rising from a chair, tremor, and increased salivation. Tr. stramonii had been taken in doses of min. 20 thrice daily for four years, larger doses not being tolerated because of dryness of the mouth and blurring of vision. (As a maximal dose this is in our experience unusually small.)

RIGIDITY IN A CASE ON VARIOUS TREATMENTS

lp = "lead-pipe" rigidity. cw = "cog-wheel" rigidity. + = rigidity just detectable. + + = moderate rigidity.
+ + + = rigidity requiring effort to produce passive movement.

Examination revealed flexed posture and festinant gait, mask-like facies, monotonous weak voice, and tremor of the left arm and of both legs, of moderate severity. Voluntary movements were slow, but muscular power was normal. Rigidity varied from day to day (a representative single finding is shown on line 1 in the accompanying table).

Inert tablets, 2 t.d.s., were administered in addition to the stramonium for a week, with no change in symptoms. Rigidity was of the same order as before (line 2 of table). Parpanit was then given in doses increasing from 0·0125 to 0·1 g. t.d.s. for three weeks, the stramonium being continued. Occasional giddiness was noted, coming on $^{1}/_{4}$–$^{1}/_{2}$ hr. after the tablets were taken and lasting up to $^{1}/_{2}$ hr. Tremor was unaffected, and festination was somewhat increased. A tired feeling in the feet was complained of. Rigidity was of the same order as before (line 3 of table). Stramonium was now reduced, and, after three weeks, omitted. The patient reported increased intermissions in his tremor, and increased ease in rising from a chair. The feet sometimes felt very heavy. Rigidity was again of the same order (line 4 of table). Without the patient's knowledge inactive control tablets of identical appearance were now substituted for the parpanit. Five days later the patient requested a visit, since he could not now attend the outpatient department because of a feeling of weakness and a difficulty in initiating movements. The previous night these had been so pronounced that he had urinated in bed, being unable to climb out. When seen, his face was a more rigid mask, his posture more flexed, and his movements slower. Tremor was notably greater, and rigidity was greater than had been found previously (line 5 of table). The patient was admitted to hospital.

He was observed for a week without any drugs being given. During this period there was no subjective or objective change, rigidity being as shown in line 6 of the table. Parpanit 0·025 g. four times daily, increasing to six times daily, was then given. On this régime, within twenty-four hours, walking became easier, posture showed a slight improvement, and the patient could get in and out of bed without difficulty. Tremor was not appreciably affected, and giddiness recurred. Rigidity decreased (line 7 of table). After parpanit had been given for eighteen days with no further change, tablets of hyoscine gr. $^{1}/_{200}$ of identical appearance were substituted, being given four times daily. The change was effected without the knowledge of the patient. The mouth became uncomfortably dry, and walking was reported as being somewhat easier, but otherwise no change was noted, rigidity being as shown in line 8 of the table. There was occasional giddiness.

After the patient had been five days on hyoscine, a return to the previous dose of parpanit was made, again without the patient's knowledge. Two days later he was told the change, and was asked which drug he preferred. could not decide. No change in his condition had b noted by the medical, nursing, or physiotherapy staff attendance; rigidity was as shown in line 9 of the table.

A further reversion to inert control tablets again precipit a relapse, and the patient was started again on parpa with a return to his previous condition on this treatm He was discharged from hospital, but on his return h he added hyoscine gr. $^{1}/_{200}$ t.d.s. to the parpanit 0·02 five times daily which he had been instructed to take. N day he called in his neighbours to help him eject imagin strangers from his room, and the following day he [illegible] his servant, already alarmed at his clumsy manipulation his cutlery at table, to eject another stranger from favourite chair. The servant informed us, and on [illegible] the patient we confirmed his ataxia, and noted unalter tremor and somewhat reduced rigidity (line 10 of tabl Parpanit dosage was halved, and there were no furth hallucinations. Giddiness however was troublesome, after a further fortnight parpanit was omitted, stramoni being given in the original dosage. Giddiness disappear The general condition was about the same as it had b on parpanit, on hyoscine, and on stramonium initial Rigidity a month later was as shown in line 11 of the tab

This patient, then, shows the day-to-day variatio of rigidity on constant treatment characteristic parkinsonism (compare lines 1 and 11 in the tabl What were considered significant changes in rigidi were seen only on the omission of all drugs (lines 5 and and on the administration of a combined parpanit a solanaceous dosage which proved toxic (line 10 of tabl No objective evidence of difference in type or deg of therapeutic activity between parpanit and solanaceo drugs was shown by this patient, who could not ev distinguish between the subjective effects. Either dru however, could prevent the severe recrudescence symptoms and signs which arose on the withdrawal all drugs.

SUMMARY

The therapeutic activity of parpanit has bee compared with that of solanaceous drugs in maxim tolerated doses in patients with parkinsonism.

Parpanit appears to have an activity comparable t that of solanaceous drugs.

The side-effects of parpanit differ in relative intensit and from those produced by the solanaceous drugs, preference for one or other treatment may be determined by this, as much as by the small differences between the therapeutic effects.

We wish to thank Dr. E. Arnold Carmichael, of the National Hospital, Queen Square, for access to the cases treated and for invaluable advice and criticism; Dr. Kurt Hartmann, of Zurich, for advice; and Pharmaceutical Laboratories Geigy and Messrs. H. R. Napp Ltd. for supplying generous amounts of drugs. The investigation was undertaken on behalf of the Medical Research Council.

FAMILIAL OUTBREAK OF STAPHYLOCOCCAL INFECTION OF BONE AND JOINT

M. H. M. HARRISON
M.B. Leeds
LATE HOUSE-SURGEON, WINGFIELD-MORRIS ORTHOPÆDIC HOSPITAL, OXFORD

STAPHYLOCOCCAL infections in a community are sufficiently commonplace to pass without comment, but this familial outbreak is reported because of two unusual features. First, in a family of seven children there were, besides multiple examples of cutaneous infections, three cases of acute infection of bone or of joint. Two children developed acute suppurative arthritis and the third an acute osteomyelitis, and all three patients were in hospital at one time. Secondly, the strain of the causal staphylococcus was found to be the same in each of these major lesions, and the same organism was recovered from other members of the same family. The family of nine live under rather crowded conditions in an Oxfordshire village. The following is a summary of the family and their illnesses:

ie.—Aged 1 year, had impetigo in January, 1947, which cleared under local penicillin therapy. *Staphylococcus aureus* (phage type 29/31) was recovered from his nasal mucosa in April, 1947.

Christopher.—Aged 3 years, had no known lesion.

Ernest.—Aged 4 years, had impetigo in December, 1946, which cleared under local penicillin therapy. He had a boil over a medial malleolus in March, 1947, and acute septic arthritis of the right knee in April, 1947. *Staph. aureus* (phage type 29/31) was recovered from the knee-joint and blood-culture. A staphylococcus recovered from his nasal mucosa was not typable.

Brian.—Aged 7 years, had impetigo and boils on his heels in January, 1947, which cleared under local penicillin therapy. He had acute osteomyelitis of left pubis and right radius in April, 1947. *Staph. aureus* (phage type 29/31) was recovered from blood-culture.

Eric.—Aged 11 years, had no known lesion.

Mavis.—Aged 12 years, had suppurative arthritis of the right hip in February, 1947. Staphylococcus (phage type 29/31) was recovered from blood-culture and hip-joint, and phage type 47 from nasal mucosa and skin swabs.

Beryl.—Aged 14, had no known lesion, but *Staph. aureus* (phage type 29/31) was recovered from her nasal mucosa.

Mother.—Aged 34, had no known lesion. An untypable staphylococcus was recovered from skin swabs.

Father.—Aged 37, had a chronic discharging ear, but no staphylococci were recovered from the discharge.

TREATMENT AND RESULTS

The three cases of bone and joint involvement were all under the care of Dr. J. Trueta in the Wingfield-Morris Orthopædic Hospital, and were all treated by a similar method.

(1) Penicillin was administered by a continuous intramuscular drip delivering 400,000 units a day as the initial dose, decreasing to 200,000 units a day as progress became satisfactory. In addition, one of the children was given sulphadiazine 14 g. by mouth.

(2) The affected part was immobilised. Ernest, with acute septic arthritis of the knee, was placed in a posterior portion of a split plaster hip spica. Brian, with acute osteomyelitis of the pubis and radius, was placed on a Robert Jones double abduction frame, and a plaster back slab was applied to the affected upper limb. Mavis, with acute septic arthritis of the hip, was placed on a Robert Jones double abduction frame.

(3) When, on the child's admission to hospital, pus was considered to be already present, the lesion was explored with a view to removing it. In Ernest's case, diagnostic aspiration of the knee-joint having yielded pus, under general anæsthesia and a tourniquet an arthrotomy was performed, the pus and fibrin were removed, and the joint was closed. On three subsequent occasions he underwent aspiration of the joint and instillation of penicillin. In Mavis's case, 35 ml. of pus was removed by aspiration from the hip-joint and replaced with penicillin.

(4) When on admission, however, the physical signs and response to treatment suggested that the lesion had not yet progressed to suppuration, conservative measures were found to be adequate. Thus Brian, who had the double bone lesion, recovered completely with penicillin treatment alone.

The results were as follows. Nine months later Ernest's knee was cool and dry, with a full range of active movement, and Brian had full function in his arm and pelvic joints with no residual tenderness. Mavis's arthritis of the hip flared up again five weeks after admission. Eleven months later she has a good gait and function, but radiography suggests some reduction of the joint space in the affected hip, and there is half an inch of real shortening and restriction of full flexion of that joint.

DISCUSSION

In all cases a blood-culture was made before treatment was begun, and any pus recovered from the cases was sent for bacteriological examination. The organisms recovered from all these children were reported as *Staph. aureus*, and all were found to have the same cultural characteristics. A further attempt was made to establish their identity by bacteriophage typing[1] and they were all reported as phage type 29/31. About half of all pathogenic staphylococci cannot be phage typed at all, but of the remainder some fifty different strains can be differentiated by their reactions. The fact, therefore, that these five strains were all of the same phage type seems a reasonable indication that they had originated from a common source.

Despite careful investigation of the home environment no direct source of the organism could be traced, but the close living conditions were almost certainly responsible for the multiplicity and persistence of the infection.

Acute pyogenic infections of bone or joint, though by no means uncommon, are not an everyday occurrence, and the surprise which greeted the arrival in the ward of the second case from the same family grew almost to incredulity when the third child appeared. I have not been able to find any comparable published report.

SUMMARY

In a family of seven children described, there were, besides multiple examples of cutaneous infections, three cases of acute infection of bone or of joint. The infecting organism was a *Staph. aureus*, demonstrated by bacteriophage typing to be the same in all three cases and the same as that recovered from the nasal mucosæ of two of the remaining four children of the family.

I wish to thank Dr. J. Trueta and Mr. J. C. Scott for their kind permission to publish these cases; Dr. J. R. O'Brien for the bacteriological examinations; and Dr. V. D. Allison, of the Staphylococcal Reference Laboratory, Colindale, London, for bacteriophage typing all the organisms.

SUMMARY

The therapeutic activity of parpanit has be compared with that of solanaceous drugs in maxim tolerated doses in patients with parkinsonism.

Parpanit appears to have an activity comparable that of solanaceous drugs.

The side-effects of parpanit differ in relative intensit from those produced by the solanaceous drugs, an

k. He also noticed, but did not date, an outcrop of ll lumps over his whole body, even in his tongue. There no history of any such disorder in his family or in his ge. His work as a sweeper entailed dealing with refuse excreta, and as in most Indian villages there were e rooting about. He had eaten pork.

He was well built and muscular, with remarkable symtrical hypertrophy of the calves (circumference of right calf 16½ in., left 18 in.). His body was studded with many hundreds of small nodules, chiefly in forehead, chin, neck, upper arms, shoulder girdle, pectorals, thighs, and lower legs. Two translucent nodules in mucosa of tongue. No abnormal signs in cranial nerves or in arms. Calf muscles very weak; and patella and achilles reflexes absent; plantar responses flexor. No sensory change.

Radiography of skull, muscles, and chest revealed no abnormality. A typical cysticercosal cyst was removed from the chest wall. Incision of calf showed whole substance of muscle superseded by a grape-like mass of many hundreds of cysts. Three were removed and again found to be cysticercosal cysts.

cercosis (case 2) ing enlarged calves.

DISCUSSION

Even without the palpation of cysts, this type of cysticercosis may be readily distinguished from muscular dystrophy by several features. Muscular dystrophy develops much earlier in life, and the latissimus dorsi cle and the lower part of the pectoralis major cle are not involved in the pseudohypertrophy ttrass 1938). In trichiniasis there may be general- muscular swelling, but the muscles are painful more obviously œdematous, and the illness is

case 1 permission to incise the calves was refused, case 2 is complementary in this respect.

case 1 the œdema and swelling of the muscles due probably to the simultaneous growth of many . MacArthur (1937) recognises an occasional lised or generalised œdematous swelling of muscles premonitory symptom. In Priest's (1926) case ly all the muscles were enlarged, especially those of shoulder girdle, giving the appearance of a powerful n of the Sandow type of development, whereas in lity the muscular power was very feeble. Manson-Bahr 45) notes that sometimes the localised intramuscular llings resemble a muscular dystrophy.

The primary undiagnosed fever in each case may present the period of invasion, comparable with the and-fly fever," "headache," "migraine," "P.U.O.," d "clinical malaria" suggested by Dixon and greaves (1944) as prodromata.

Case 1 almost certainly had a cyst in the left frontal a, and the initial provisional diagnosis of frontal mour, based on headache; changed personality, a right sp reflex, and a right extensor plantar reflex, had not n far short of the mark. The later development of lariousness, joking, and almost *Witzelsucht*, with a ised cell count and protein in the C.S.F., makes the milarity closer still.

The eosinophil response has been of little diagnostic value previously (MacArthur 1933–34, 1937, Dixon and Hargreaves 1944), but it was the sudden appearance of moderate eosinophilia coupled with the palpation of three cysts that led to the diagnosis in case 1. Eosinophilia was absent when only one cyst was palpable in November, 1944. The moderate eosinophilia which later developed remained unchanged for more than four months before returning to normal. MacArthur believes that an eosinophilia may develop when the cysts are breaking down and liberating their contents, but the onset of eosinophilia in case 1 coincided approximately with the appearance in the muscles of many viable cysts. Lipscomb's (1935) case showed an eosinophilia of 12%, associated with fever, three other counts in apyrexial periods being normal for eosinophils.

The present two cases also confirm the opinion of Dixon and Smithers (1934) that the palpable subcutaneous cyst may be alive.

Menon and Veliath (1940) found at necropsy that the most notable feature in the histology of the cyst wall in the brain was a plasma-cell reaction in the capsule, and suggested that a cytological study of the C.S.F. for the demonstration of these cells might prove of diagnostic importance. With this in view the fluid was re-examined under the most favourable conditions possible, but no plasma cells were seen after a long search.

At no time in case 1, even when there was well-marked eosinophilia in the blood, were eosinophils seen in the C.S.F., in contradistinction to the case reported by Applebaum and Wexberg (1944) where a normal blood-count was associated with an eosinophilia in the C.S.F.

On the assumption that a single invasion had taken place and that the patient was not harbouring *Tænia solium* and so reinfecting himself, it may be that the tissues were simultaneously involved and that different cysts matured or overcame local resistance at different times. This in no way invalidates the statement in the *British Medical Journal* (1941) that "within one month of the ingestion of ova the parasites begin to develop in favourable sites and that within four months the embryo is fully formed within its cyst." This will explain the appearance of a cyst or cysts in the frontal lobe in January, 1944; another cyst in the lip in November, 1944; three subcutaneous cysts and generalised myositis in February, 1945; and crops of subcutaneous cysts at different times since. This further is in accord with the statements of MacArthur (1937) and Brailsford (1941) that there is a latent period of some years between the ingestion of the ova and the appearance of the nodules. It is also in harmony with Brailsford's belief that auto-infestation is rare, and that most cases are due to ingestion of ova. Moreover, since the worm grows to a normal length of 6–10 ft., it must be almost impossible for proglottides to regurgitate through that length of bowel, and auto-infestation, if it does occur, must occur comparatively early.

Apart from their intrinsic value these cases are of topical interest in that, with the return of so many men from India and the Far East, the incidence of cysticercosis will probably increase in this country.

SUMMARY

Two cases of generalised cysticercosis are described, where the outstanding feature was generalised pseudohypertrophy of muscles.

One patient was observed for 18 months, during which he developed an eosinophilia which coincided with the appearance of many viable cysts in the muscles.

It is suggested that in this case generalised muscular infestation occurred on one occasion only, the cysts developing in favourable sites first and in less favourable sites later.

I am indebted to Brigadier J. D. S. Cameron, C.B.E., for his encouragement to publish this paper: Colonel F. M. Lipscomb, O.B.E., for his criticism; Major L. Krainer for his reports on the sections and the C.S.F.; Major A. D. Leigh,

CYSTICERCOSIS RESEMBLING MYOPATHY

R. J. McGILL
M.B. N.Z., M.R.C.P.E.
LIEUT.-COLONEL, INDIAN MEDICAL SERVICE (RETD)

THE two cases reported here present features which emphasise MacArthur's (1937) dictum that the different types of cysticercosis described are but isolated phases in the natural history of the disease.

CASE-RECORDS

Case 1.—A Sikh sapper, aged 25, who had been 2½ years in the Army at Poona, and, before that, 7 years huntsman to the Maharaja of Patiala, was admitted to hospital on Feb. 11, 1944, with 4 months' history of weakness, 2½ months' history of bilateral anterior temporal headache of equal intensity day and night but not interfering with sleep nor accompanied by vomiting or any visual or auditory change, and 2 days' history of fever and rigors.

The patient moaned often, gave his history with difficulty, and was uncoöperative. He was right-handed. The only abnormalities found were a palpable spleen, an extensor plantar reflex on both sides, impairment of the sense of position of the right great toe, and a right grasp reflex. Retinæ normal. The psychiatrist reported as follows: "He knows that there is a change in his mind. He says that he understands well enough, and that he knows what he wants to say, but he cannot get it out. His difficulty in speaking is obvious—slow, distinct, delayed. There is ideational retardation, and a tendency in his conversation to wander away from the subject, but he endeavours to return to it."

White-cell count 6800 per c.mm. (polymorphs 70%, lymphocytes 25%, eosinophils 3%, monocytes 2%). Urine: no abnormality. Stools: no ova or cysts. Blood Wassermann reaction and Kahn test negative. On March 25, 1944, lumbar puncture produced clear cerebrospinal fluid (C.S.F.) under normal pressure, containing 1 cell per c.mm., protein 30 mg. per 100 ml., chlorides 750 mg., sugar 150 mg., and urea 38 mg. Encephalogram and radiogram of skull normal.

April 11, 1944: pyrexia and rigor; no malaria parasites found in blood. April 12: white-cell count 8000 per c.mm. (polymorphs 72%, lymphocytes 20%, eosinophils 5%, monocytes 3%). After two months in hospital, all abnormal signs having disappeared and headache having much improved, patient went home on leave. It was felt at that stage that the former provisional diagnosis of a left frontal tumour could not be substantiated.

Readmission.—On Nov. 16, 1944, he was admitted to the psychiatric department, with the diagnosis of anxiety state. He was then complaining of generalised headache and swelling of the body. His face looked bloated; there was a left mastitis, and a small submucous tumour in the upper lip. Other cysts were sought for without result. The only abnormality was a persistent extensor plantar reflex on the right side. Blood-pressure 110/78. White-cell count 6400 per c.mm. (polymorphs 73%, lymphocytes 20%, eosinophils 5%, monocytes 2%). Lumbar puncture produced clear C.S.F. under normal tension, with 6 lymphocytes per c.mm., protein 50 mg. per 100 ml., sugar 45 mg., Wassermann reaction negative. Urine normal; no ova or cysts in stools. Psychiatrist's report: "A cavalier attitude. Emotionally very superficial and apathetic. Conversation tends to be stilted. Appreciable tendency to echo symptoms. Orientation and memory fair. ? visual hallucinations, but very haphazard in answers. No emotional change in his speech or actions. ? commencing behaviour disorder. No ideational disorder, but there is some retardation."

The patient's symptoms much improved and he was discharged on Jan. 7, 1945.

Third Admission.—He was admitted for the third time on Feb. 5, 1945, complaining of weakness and increasing girth of his calf muscles and a constant bilateral frontal headache, worse on the right side. His intelligence was normal, his memory was good, and he gave a connected story, but he was boisterous, childish, and addicted to cracking jokes, and he laughed often without apparent cause. He was the life and soul of the ward. He was docile and he assisted the nurses in their work; he knew the use of objects and could use them, but it was difficult to make him grasp what wa necessary. His appetite was now voracious. There wa apparent hypertrophy of all muscles of the body, a veritabl Hercules, the right calf was 15 in., and the left calf 15½ in in circumference. (The admitting officer had provisionall diagnosed pseudohypertrophic muscular dystrophy.) The was slight œdema over small of back and over the shins f their whole length. Small subcutaneous nodules, about t size of a pea, were found over the left scapula, mid-sternu and right forehead. The submucous tumour noticed in t upper lip in the previous November had disappeared. Fun and visual fields normal. Bilateral extensor plantar refle White-cell count 6600 per c.mm. (polymorphs 68%, lymph cytes 18%, eosinophils 10%, monocytes 4%). No ova cysts in stools.

Cysticercosis was provisionally diagnosed and confirm by examination of an excised cyst.

C.S.F.: *pressure normal* (145 mm.), 20 lymphocytes p c.mm., protein 55 mg. per 100 ml., globulin (Nonne-Appel increased, Lange 4332000000, Wassermann reaction negativ Blood-cholesterol 150 mg. per 100 c.cm., blood-urea 32 m Radiography of a thigh and the skull showed no calcif foci or other abnormality; sella and clinoid processes norm Treatment with *Filix mas* on two occasions had not produc any tapeworm in stools; and stools were negative for o in repeated examinations over nearly a year.

Course of Illness.—Feb. 17, 1945 . generalised epileptifor fit; no incontinence of urine or tongue-biting, but furth details not available. No further fit occurred until 8 mont later. March 24: many more cysts palpable, and ma seen, in forehead, right cheek, tongue, right anterior cervi region, left suprascapular fossa, left antecubital fossa, anter and lateral aspects of chest, left infrascapular area, and l lower quadrant of abdomen. All but one of the cysts abo horizontal nipple line could be palpated. April 30: m cysts appeared about neck. May 15: C.S.F. contain 18 cells per c.mm. (lymphocytes 88%, polymorphs 12% protein 70 mg. per 100 ml. Pandy test +, and Nonne-App test negative. May 19: White-cell count 6200 p c.mm. (polymorphs 61%, lymphocytes 27%, eosinophils 9 monocytes 3%). June 7: white-cell count 6400 p c.mm. (polymorphs 63%, lymphocytes 25%, eosinoph 10%, monocytes 2%). June 11: radiography of calf showed fine diffuse mottling throughout soft tissues but calcification.

June 17, 1945: right plantar reflex still extensor; rig *abdominal reflexes less brisk than those on the left.* Ment condition had gradually improved. Patient had headache, relieved by recumbency and not worse on lean forward. He still complained of tightness of calf muscle whose circumference and overlying œdema were unchange He was quiet and had lost his boisterousness. He was mo helpful than ever in the ward. Memory for recent and pa events good. He was suffering from insomnia, sleepi only from 5 to 8 A.M. and sometimes during the da Emotions apparently normal; no hallucinations or delusion No defects in articulation; no aphasic signs, spoken an written speech being normal. No phenomena associate with aphasia, such as amimia, the inability to understa symbols or to recognise common objects; no apraxia. Cys more numerous than before; two excised on May 18 were st viable.

Sept. 13: headache and tightness in calves and pector muscles only slight. Patient alert and intelligence norma Girth of all muscles unchanged; slight œdema still prese over shins. Liver and spleen just palpable. Blood-pressu 96/66. Cysts unchanged in number and consistency. Plant reflex still extensor; right abdominal reflexes diminished.

White-cell count 6400 per c.mm. (polymorphs 67% lymphocytes 24%, eosinophils 7%, monocytes 2%). Urin normal. Erythrocyte-sedimentation rate 35 mm. in 1 hour Patient was pitifully weak and tired easily.

In October and in November an epileptiform fit wa witnessed. In December, his condition unchanged, the patien left on pension for his home in the Punjab.

Case 2.—A Hindu sweeper, aged 20, complained of year's weakness and swelling of the legs. A year previousl while on a long ride, he had been overcome with weakne and fever, and on his return had lain ten days prostrate with fever and limb pains. He then returned to work but in the subsequent 12 months he noticed that his calve were increasing in size (see figure) and his legs becoming a direct lethal action on them. Similarly, the ilariæ remain actively motile for more than 48 hours at 37°C in the presence of serum from rats treated with doses of hetrazan 1½–2 hours before bleeding. So ems that hetrazan is not converted in the body some other substance which is actively micro- icidal. This conclusion is further supported by the rvation that intrapleural injection of hetrazan does have any striking action on the microfilariæ in the ral cavity.

Further studies were made by examining the distri- ion of microfilariæ in the different organs. Sections e made by the usual histological methods, and the ber of microfilariæ per unit area was determined counting under the microscope. In a typical experi- t a piece of liver was removed under anæsthesia a rat whose blood contained 470 microfilariæ per c.mm.; the section of liver contained 44 microfilariæ 100 sq. mm. Hetrazan (25 mg. per 100 g.) was then ed intraperitoneally, and an hour later the rat killed. The number of microfilariæ in the peripheral had fallen to 85 per 10 c.mm., and the number ctions of the liver had risen to 193 per 100 sq. mm. rats killed within an hour of treatment with hetrazan microfilariæ lay between the liver cells, presumably collapsed sinusoids. In rats killed 6 hours after ment many of the microfilariæ were surrounded by ytes, which seemed to be attacking them. In of the other tissues the microfilarial content was , relative to the initial blood-count, in treated rats in untreated controls. The lungs form a special in cotton-rat filariasis since they are the chief of entry for the microfilariæ from the extravascular (pleural cavities) into the circulation, and their nt of microfilariæ is correspondingly high.

is concluded from all the above-mentioned observa- that hetrazan acts by modifying the microfilariæ e way so that they are seized by the phagocytes reticulo-endothelial system and presumably d; thus its action would resemble that of . Microfilariæ which are removed from contact hagocytes—e.g., in vitro, or in the pleural cavity— speedily affected by hetrazan.

chemical and/or physical reactions underlying "opsonising" effect of hetrazan are unknown. the effect is produced so quickly, they must be . Attempts were made to antagonise the action of n by previous administration to the cotton-rats stances such as nicotinamide, nikethamide, &c., have a somewhat similar chemical structure. In cases the disappearance of microfilariæ caused by an was less complete than usual, suggesting slight nism; but convincing antagonism was not strated. This work will be continued, but various stances will prevent its completion and full ation in the next twelve months.

SUMMARY

action of hetrazan (1-diethylcarbamyl-4-methyl zine hydrochloride) on cotton-rat filariasis due to *oides carinii* has been studied.

compound acts on the microfilariæ more than on dult worms.

compound and its metabolic products do not have ct lethal action on the microfilariæ, but they seem dify them in some way (opsonise them) so that are seized by phagocytes of the tissues and removed the circulation.

ful acknowledgments are due to Mr. D. Garlick and R. Jones for technical assistance.

Reviews of Books

Living Anatomy

R. D. LOCKHART, M.D., CH.M., regius professor of anatomy, University of Aberdeen. London: Faber. 1948. Pp. 71. 12*s*. 6*d*.

THIS is an atlas of 149 photographs demonstrating surface contours and the actions of muscles in the living (particularly the male) subject. The purpose of these excellent illustrations is to promote enthusiasm for the examination of muscles in action in the living body. Several photographs are added at the end of the book, affording comparisons between virgin and lactating breasts, and the male and female forms: 6 photographs are also devoted to the surface anatomy of the eye, and 5 to the superficial veins of the forearm. Since at most anatomy schools a knowledge of muscle action is only a part of the knowledge of surface anatomy required of the medical student, this book may perhaps not have much appeal to him; the surface relations of the major arteries and nerves, for example, might be thought of greater importance for the future general practitioner. The atlas should, however, be of considerable use to occupational therapists, masseurs, and teachers of physical training, and also to artists. Since the late Arthur Thomson's *Handbook of Anatomy for Art Students*, now lamentably out of date (although still reprinted), little or no attempt has been made in this country to present surface anatomy to the artist by means of the photography of well-selected models. Here, in Professor Lockhart's atlas, is a series of photographs well suited to this purpose.

Blood Derivatives and Substitutes

C. S. WHITE, M.D., SC.D., formerly professor of surgery, George Washington University; J. J. WEINSTEIN, M.D., associate in surgery at the university. Baltimore: Williams and Wilkins Company. London: Baillière. 1947. Pp. 484. 41*s*.

THE authors say that their book is written "for the purpose of presenting a comprehensive study of plasma, plasma substitutes and by-products from a clinical standpoint," and "the chief emphasis has been placed on the practical and clinical aspects of the various subjects covered, so that it may serve as a reference and guide equally for the surgeon, the internist, pathologist, general practitioner, and student"—a fairly comprehensive field of readers. After a brief survey of the history of transfusion, a chapter describes the physiology and chemistry of the plasma, including a cursory discussion of the blood-groups. Between two-thirds and three-quarters of this chapter are taken up by the details of technical methods for counting blood-cells, the micro-Kjeldahl technique, and the like. The preparation of liquid citrated plasma (assisted by Dr. J. Reichel), the storage of plasma, the preparation, storage, and use of dried plasma (by Dr. E. L. Lozner), and the administration of plasma are then described. Chapters follow on plasma fractionation (by Dr. S. T. Gibson), by-products of plasma preparation, plasma substitutes, human blood-serum, blood preservation, the blood bank (by Dr. R. B. H. Gradwohl), shock, clinical results with human plasma, and reactions with plasma.

The book is of value for two reasons: it is largely an account of the personal experience of the authors in the Gallinger Municipal Hospital, Washington, where a blood-plasma bank has been maintained since 1937, and it presents a general review of work (mainly American) on blood derivatives and substitutes during the war years. It is, however, unequal in its treatment of the various subjects. It seems a pity that a book nominally concerned with blood substitutes does not contain a more complete account of the work done on them: they are dismissed in 28 pages, and no mention is made, for example, of 'Periston,' or the Swedish work on 'Dextran.' Homologous serum jaundice, which must be considered one of the risks of using plasma, is discussed in less than a page, reference being made to only four papers, none of them later than 1944, while the chapter on plasma fractionation and fractions concerns itself almost exclusively with albumin. On the other hand, space has been given to subjects which might well have for the notes and photograph of case 2; and the D.M.S., India Command, for permission to publish.

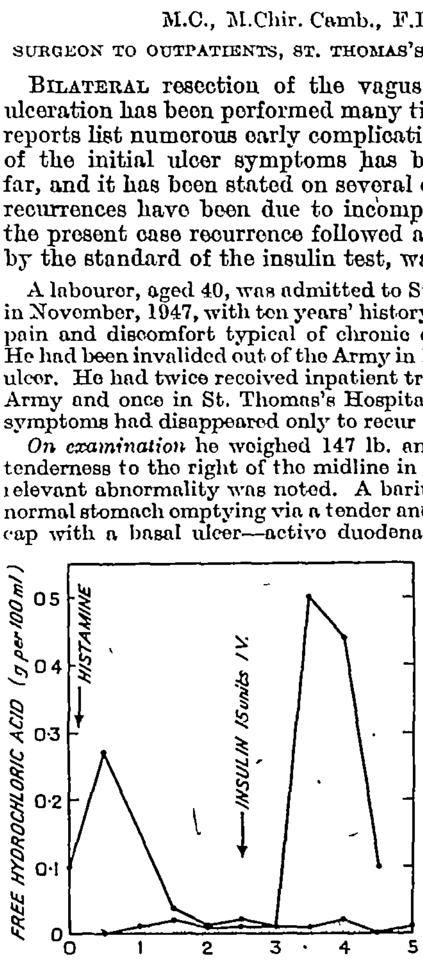
RECURRENCE OF DUODENAL ULCER SIX MONTHS AFTER ADEQUATE VAGOTOMY

C. G. ROB
M.C., M.Chir. Camb., F.R.C.S.
SURGEON TO OUTPATIENTS, ST. THOMAS'S HOSPITAL, LONDON

BILATERAL resection of the vagus nerves for peptic ulceration has been performed many times. All published reports list numerous early complications, but recurrence of the initial ulcer symptoms has been uncommon so far, and it has been stated on several occasions that such recurrences have been due to incomplete operation. In the present case recurrence followed an operation which, by the standard of the insulin test, was adequate.

A labourer, aged 40, was admitted to St. Thomas's Hospital in November, 1947, with ten years' history of upper abdominal pain and discomfort typical of chronic duodenal ulceration. He had been invalided out of the Army in 1944 with a duodenal ulcer. He had twice received inpatient treatment, once in the Army and once in St. Thomas's Hospital, but each time his symptoms had disappeared only to recur soon after discharge.

On examination he weighed 147 lb. and, apart from some tenderness to the right of the midline in the epigastrium, no relevant abnormality was noted. A barium meal showed "a normal stomach emptying via a tender and deformed duodenal cap with a basal ulcer—active duodenal ulceration." The gastric acidity after histamine followed by 15 units of insulin is shown in the accompanying figure.



Gastric acidity before and after vagal resection: upper curve, before resection (blood-sugar 52 mg. per 100 ml.); lower curve, twelve days after resection (blood-sugar 48 mg. per 100 ml.). The response six months later, when symptoms had recurred, was no free hydrochloric acid, combined hydrochloric acid 0·03 g. per 100 ml. as highest level after insulin 15 units I.V., and blood-sugar 34 mg. per 100 ml.

Operation.—On Nov. 7, 1947, a resection of the vagus nerves by the transhiatal route was performed, and an active ulcer was noted on the anterior wall of the first part of a scarred and deformed duodenum. There was stenosis.

The postoperative course was uneventful, and the patient was symptom-free and very satisfied on his discharge fourteen days later. A postoperative insulin test was performed before he left hospital and the vagus-nerve resection appeared by this standard to be adequate (see figure).

Recurrence.—The patient remained very satisfied for six months; he gained 6 lb. in weight and even recommended the operation to two of his friends. In May, 1948, however, he reported with a complete recurrence of his symptoms and was of the opinion that his ulcer had recurred because he fel just the same as he had before the operation. A barium me now showed "a normal orthotonic stomach emptying via tender and deformed duodenal cap—appearance of activit in a duodenal ulcer." In view of this report a third insuli test was performed. There was no free hydrochloric aci and only a slight trace (0·5%) of combined acid was presen The blood-sugar level fell to 34 mg. per 100 ml.

COMMENT

By the standard of the insulin test this patient had a adequate resection of the vagal nerve-supply to h stomach, and there is no evidence of regeneration. I spite of this his ulcer symptoms have recurred after s months' complete postoperative freedom.

The barium meal, though not demonstrating a defini ulcer, now shows the appearance of activity in a tend duodenum, and the insulin test performed after t recurrence of symptoms produced no free hydrochlo acid and only a small amount of combined acid.

At St. Thomas's Hospital vagus-nerve resection h been performed on 37 patients for peptic ulcer. The ea results in 5 patients with secondary ulceration followi gastrectomy or gastro-enterostomy have been very go In the other 32 patients with duodenal ulcer numero initial complications have been noted, including te porary severe dysphagia (4 patients); persistent di rhœa (2 patients); and eructations of foul gas (1 patient but in no other patients have the ulcer sympto recurred, though in 4 the operation was by the standa of the insulin test incomplete.

Preliminary Communication

MODE OF ACTION OF HETRAZAN IN FILARIASIS

'HETRAZAN' (1-diethylcarbamyl-4-methyl piperaz hydrochloride) is a new compound which has recen been introduced for the treatment of human filaria due to *Wuchereria bancrofti*.[1] We report here an inve gation carried out on cotton-rat filariasis to study mode of action.

The cotton-rats used for this work were infected our laboratory with *Litomosoides carinii*. In this infe tion the adult worms lie in the pleural cavities and t microfilariæ, which are sheathed and non-periodic, flo in the circulating blood. When the infected cotton-ra are treated with hetrazan in doses of 25 mg. per 100 of body-weight intraperitoneally, the microfilariæ in t peripheral blood become much fewer.[2]

When 6 mg. per 100 g. is injected intravenously in cotton-rats, the diminution is extremely rapid, 80 of the microfilariæ disappearing in 1 min., and ov 90% in 2 min. But even after fairly intensive treatme a few microfilariæ still persist in the circulating bloo Similarly, the pleural cavities still contain many moti and apparently healthy microfilariæ around the adu worms. It seems that these microfilariæ in the pleur cavities form a reservoir from which the supply in t blood is constantly replenished. Hetrazan has only moderate effect on the adult worms, and our experien confirms the report of Hewitt et al.[2] that prolong intensive treatment is needed to destroy them: eve this sometimes does not kill all the worms.

Microfilariæ of *L. carinii* can be maintained alive f several days at 37°C in a suitable medium—e.g., seru plus Ringer's solution plus glucose. When hetrazan added to the medium in concentrations up to 100 mg per 100 ml., the microfilariæ remain actively motile f more than 48 hours, indicating that hetrazan does no

THE LANCET

LONDON: SATURDAY, NOV. 6, 1948

Streptomycin in Pulmonary Tuberculosis

Two years ago the Medical Research Council appointed a committee, with Dr. GEOFFREY MARSHALL as chairman, to plan clinical trials of streptomycin in tuberculosis. The committee's first major report, on tuberculous meningitis,[1] confirmed the American experience that in most cases streptomycin would prolong life, that in many it would produce considerable improvement, and that in a few clinical cure was possible—a great advance over the previous hopelessness. The committee's second report,[2] on pulmonary tuberculosis, is also favourable within limits; but whereas the meningitis trials embraced every variety of case, save those in extremis, the pulmonary series was restricted to one category. This category—acute progressive bilateral tuberculosis of recent development in young adults—is peculiarly unsuitable for collapse therapy, but, judging from animal experiments, it is one in which the antibiotic might be expected to have some action. Bearing in mind the shortage of supplies, it was fully justifiable to treat half the patients (S) with streptomycin plus bed-rest and the other half (C) in the ordinary way, by bed-rest alone. The method adopted in assigning patients to streptomycin and control groups, and the precautions taken against bias in the selection of patients, in treatment, and in the analysis of results, have brought this controlled study as near to a laboratory experiment as is practicable and make it unique in the dismal history of tuberculosis chemotherapeutic trials. The 55 S patients received 2 g. of streptomycin daily intramuscularly for four to six months (mostly for four). At the end of six months 4 S patients and 14 of the 52 controls had died, whereas 28 S patients and 4 C patients had considerably improved. Improvement was assessed by X-ray films—viewed independently by two radiologists and a clinician—clinical picture, and tendency to sputum-conversion. The radiological improvement consisted mainly of a clearing of "exudative" lesions; large cavities did not close. In general the results are definite and striking, the comparison with the control group permitting of a critical assessment capable of statistical test. It is not so much a question of "cure"—none of the treated patients could be said to be clinically cured after six months' or even a year's observation, and no more than 15% had become bacteriologically negative—as of setting the patient on the road to recovery with the aid of his own resistance, or of making the lung condition suitable for collapse measures.

The main value of the trial was to give an unequivocal affirmative to the question: Is streptomycin good in pulmonary tuberculosis? Since the subacute or acute type of disease investigated is uncommon, the direct application of the favourable conclusion is limited. But since the outstanding effect of the antibiotic was to check or cause regression in "infiltrative," "exudative," or "pneumonic" changes in the lung, benefit would be expected in other forms of pulmonary tuberculosis in which such lesions predominate. Thus we can now begin to define the types of pulmonary tuberculosis in which streptomycin can assist the conventional forms of treatment. Two things must be kept in mind. First, though toxicity did not necessitate the cessation of treatment in any case, vestibular damage was frequent (as has been the experience of others); and uncompensated vestibular damage may make a person incapable of driving a car or of walking steadily in the dark. So serious is the prognosis of the category investigated that nobody would hesitate to use the drug on account of this risk (the same is true in meningitis), but the position is different in the types of tuberculosis where the outlook is good without streptomycin. Secondly, the well-known tendency of streptomycin-resistant tubercle bacilli to emerge in the course of treatment was experienced in this trial and may account for the flattening out of the curve of improvement in many cases: improvement was nearly always greatest in the first month or so. Since no recent variation of the scheme of dosage or rhythm of administration of streptomycin has done more than postpone the appearance of drug-resistance, this dialectical phenomenon of nature is with us till further notice. This means that the physician must plan his long-term campaign of treatment on the assumption that probably only one effective course of streptomycin can be given; and if streptomycin is given during a phase of the disease in which good progress would be expected with ordinary management, a critical phase occurring later might find the weapon useless. We can roughly define the field of streptomycin therapy in pulmonary tuberculosis as cases in which the lesions requiring treatment are of recent development, progressive, and unlikely to benefit from ordinary treatment (e.g., bed-rest or collapse measures) alone. This definition would include rapidly advancing disease where pneumothorax is contra-indicated, and acute "spreads"—e.g., after artificial pneumothorax or thoracoplasty (no evidence has yet been produced to show the value of streptomycin in *preventing* spreads after ordinary thoracoplasties); lesions too "hot" for immediate pneumothorax treatment might be made suitable by a course of streptomycin. The definition will exclude old chronic fibroid, or fibrocaseous lesions, or long-standing cavitation—i.e., the commonest type of chronic phthisis. It will exclude terminal conditions, and also minimal early lesions with favourable prognosis. The main reason for excluding the "good chronic" and terminal conditions is that little benefit can be expected, and that a focus of dissemination of streptomycin-resistant bacilli will probably be created. On the other hand, the minimal or early lesion is very likely to benefit, at least temporarily; but this chance has to be balanced against the risks of streptomycin-resistance spoiling the patient's chances in a later recrudescence, and of the occurrence of permanent vestibular symptoms.

[2] *Brit. med. J.* Oct. 30, p. 769.

been omitted, or treated more briefly. The dilemma which seems to have faced the authors was how to write a book on blood derivatives and substitutes without covering, more or less completely, the whole field of transfusion.

Though not received for review until the middle of 1948, it was published in the United States in 1947. Hence the reader who expects to find references to work later than 1946 will be disappointed.

Education and Health

R. GAMLIN, M.A., M.B. Camb., chief assistant school medical officer, Liverpool. London: J. Nisbet. 1948. Pp. 372. 12*s.* 6*d.*

IT has long been recognised that teachers in training deserve good teaching in the bases of health. This book provides them with a sound complement to the standard works on school hygiene. There are excellent chapters on intelligent thinking, backwardness, scientific estimation of hearing, and immunity. Burt's finding that girls given periods of rest showed greater improvement in arithmetic than those given coaching is instructive; and so is an experiment from Georgia where 18 children picked as likely to fail in their examinations were given complete dental treatment—with the sequel that at the next examination, 17 passed in every subject. In the next edition Dr. Gamlin might mention Bowlby's work on the origin of delinquency, and bring the chapter on dietetics up to date with an account of rationing. The suggestion, recorded as "novel," that children should be taught by "participatory" rather than "rivalry" methods deserves to have as a footnote Dr. Johnson's remark: "By exciting emulation and comparisons of superiority, you lay the foundations of lasting mischief; you make brothers and sisters hate each other."

This book could usefully be read by candidates for the D.C.H.

Oxford Essays on Psychology

WILLIAM BROWN, D.M., D.SC., F.R.C.P., formerly Wilde reader in mental philosophy and director of the Institute of Experimental Psychology, University of Oxford. London: Heinemann Medical Books. 1948. Pp. 148. 10*s.* 6*d.*

IN these lectures to students Dr. William Brown seems to be restraining himself. From time to time, by a particular turn of phrase or concept, the fact that he has made a contribution to psychiatry becomes suddenly evident to the attentive reader. More often, unfortunately, the effect is of an academist presenting his subject to the young. Dr. Brown is too serious and brilliant a student of philosophy, psychology, and human nature to say things that should not be said; moreover, the impression he gives that he is not saying anything new is not entirely true. He is certainly presenting his own standpoint, and it bears the stamp of insight, erudition, and individuality. His views on Nazi Germany, the paranoid tendency, and mental relaxation all strike a note of truth, but the reader seeks in vain for a sense of the immediacy of that truth. Dr. Brown's truth is apposite; it is not insistent.

Le foie vasculaire: angiosclérose hépatique

MAURICE FAVRE, professeur à la Faculté de Médecine de Lyon. Paris: Masson. 1948. Pp. 99. Frs. 220.

THIS monograph is devoted to the morbid anatomy of a peculiar form of hepatic fibrosis of which 50 cases have been studied by the author. The condition is readily distinguishable from Laennec cirrhosis in that the fibrosis is confined to the portal tracts and does not invade the hepatic lobules. No single ætiological agent is held responsible, but the condition is regarded as a standard type of response of the portal connective tissue to injury mediated via the blood-vascular system. The evidence on which this theory is based is tenuous and leads to the remarkable conclusion that the portal fibrosis in congestive cardiac failure is not the result of the failure but is to be attributed to the same factors as are responsible for the cardiac lesions themselves. The anatomical account of the condition is presented in great detail with many clear illustrations. The tissue lesion is remarkable, and it is surprising that it has been overlooked for so long. This may be explained part however, by the absence in uncomplicated cases of a symptoms or signs referable to the liver itself. Desp its disappointing discussion on the ætiology, the bo is an extremely interesting account of vascular disc of the liver, a subject hitherto much neglected.

Black's Medical Dictionary (10th ed. London: A. & Black. 1948. Pp. 995. 25*s.*).—The present edition of the l Dr. J. D. Comrie's justifiably popular work, first published 1906, has been revised by Dr. W. A. R. Thomson. It is mu more than a dictionary, in that it gives not only definitic but also varieties, causes, and treatments of diseases; d cusses the disposal of the dead and of refuse and sewag shows the reader how to change the sheets in a bed occup by a patient; and contains much other practical informati There are over 500 illustrations in the text and 6 full p plates, of which 4 are coloured.

Modern Treatment Year Book 1948 (London: T *Medical Press.* 1948. Pp. 338. 15*s.*).—Once again Cecil Wakeley has cast his net wide in his laudable atte to provide the general practitioner with a concise pract account of modern methods of treatment. The 38 arti in the present volume cover most of the commoner (and sc of the rarer) conditions encountered in practice. It is to hoped perhaps that practitioners will not follow the advice the chapter on pernicious anæmia, not to worry abou complete hæmatological examination in a case of "suspec anæmia" until a few weeks' treatment with iron has fa to produce any improvement; and the chapter on asthm children suffers from a lack of discrimination. On the wh however, this is a book which the busy general practiti will find of value.

Oxidation-Reduction Potentials in Bacteriol and Biochemistry (5th ed. London: Staples Press for *Hospitals and Medical Services Committee of the Lon* County Council. 1948. Pp. 130. 4*s.* 6*d.*).—Since its publication in 1931 this concise book by Mr. L. F. He PH.D., has been in constant demand, as indeed it deserve be, for it is a plain straightforward account which cont not to sacrifice accuracy to simplicity. The war has responsible for a delay of nearly twelve years since the edition, and consequently much new work is summ here; thus there is a short but useful chapter on polarog and a brief description of potentiometric work with a biotics and chemotherapeutic agents. Even in its p cover, this book provides a welcome example of val money.

Endocrine Therapy in General Practice (6th ed. Chic Year Book Publishers. London: H. K. Lewis. 1948. Pp 23*s.* 6*d.*).—Dr. E. L. Sevringhaus gives us a short, sim readable book. Descriptions of the endocrine syndrome brief, but on the whole clear and up to date, with mention of latest diagnostic tests. The author is rather optimistic ab the efficacy of pituitary extracts, especially the growth fac and to a lesser degree the gonadotrophins. It is refreshin find that he devotes a fifth of the book to the therapeu of diabetes mellitus, which is as yet scarcely regardc an endocrine problem in this country. He is conservativ his estimate of the rôle of thiouracil in the treatmen thyrotoxicosis, and perhaps a little old-fashioned in recommendations about deep X-ray therapy to the thy gland. Under the heading of the mammary glands, no men is made of the use of iodinated proteins to stimulate lactat In a good chapter on the adrenals the complex interrelat of Cushing's syndrome and adrenocortical over-activity rather summarily dismissed. Gynæcological endocrinol receives too little consideration: such recent therape successes as the control of excessive bleeding with œstrog and progesterone are not mentioned, and Dr. Sevringh deprecates the use of androgens, ignoring their spectac anabolic effects in the treatment of Simmonds's disease eunuchoidism. He lays due emphasis on dietary restricti in the treatment of obesity and provides useful tables show how to plan 1200-calorie diets. The photographs are excell and depict many typical examples of endocrine disord References to commercial therapeutic products are based the American market and may therefore be confusing to English reader, but the book is a well-balanced exposition modern endocrine therapy.

When it is realised that about half of all healthy ults harbour coagulase-positive staphylococci in eir nose, and that upwards of 20% are hand carriers. ere is no need to stress the importance of widening field of investigation of the epidemiology of phylococcal infections. The squamous epithelium the nasal vestibule is considered to be the focus of nisation[9] of *Staph. pyogenes*, and HOBBS and her eagues[10] have shown that in sycosis barbæ the ecting type of staphylococcus is regularly present the nose, where it will provide an autogenous rce of reinfection unless the nasal passages are ated at the same time as the lesions. On p. 727 RRISON records a familial outbreak of staphylococcal ections in which 2 of a family of 7 children developed ute suppurative arthritis, and a third acute osteo-elitis, all within three months. The same phage pe of staphylococcus was isolated from the lesions all 3, and also from the nose of a brother recently overed from impetigo and from the nose of a sister th no history of acute infection. This is a striking ample of the epidemic potentialities of staphylococcal infections in the home, and it makes one wonder ether multiple staphylococcal infections of the n in a household may not also be due to the spread a single strain of staphylococcus from person to son. In his daily round the doctor often sees a e of impetigo associated with an earlier or sub-uent case of skin infection in one or more members the family; this may take the form of another e of impetigo, or of boils, styes, acneform pustules, fingers, or even sycosis barbæ. The infectivity contagious nature of staphylococcal infections e skin are probably not generally realised, and el—in particular the roller towel—and other of toilet used in common by all the house- probably play an important part in their d.

e is a fruitful field for further investigation the epidemiology of staphylococcal infections in the home and in industrial occupations. e occupations appear to be associated with an cal prevalence of boils and infected hands: ent statistical study[11] of the incidence of infections the skin among workers in three factories has shown reat increase in incidence over four years, the ase being greater in women than in men. It ld be interesting to know whether this prevalence demiological or is mainly attributable to contact the skin with industrial oils, chemical solvents, &c., h lower the natural resistance of the skin to tion with the patient's own skin organisms. he home only the doctor can assess the part of staphylococcus in family infections. If it appears be playing a significant part, then typing of hylococci isolated from the patient's lesion, nose. d skin, and from the nose and skin of other members the household, might yield valuable confirmatory mation. Meanwhile, it should be recognised a household in which there is a case of impetigo. ls, or a septic finger should take precautions as t as careful as those recommended in a case of bies.

The New Zealand Experiment

TEN years after the passing of the Social Security Act, the government and the profession in New Zealand agree that public medical care under the Act requires review, or (as a correspondent on p. 743 puts it) needs a spring-clean. The report lately produced by a joint committee representing the department of health and the British Medical Association reveals shortcomings and suggests some remedies.

Pride of place is given to the general-practitioner service, on which the emphasis has always been placed in developing the system. One of the interesting features of this service is that although the Act allows payment by capitation fee or by salary, nearly all practitioners outside Maori settlements and other under-privileged areas have chosen to be paid on an item-of-service basis, the fee for each item being claimed from the government either by the doctor himself (direct payment) or by the patient (refund system). Each item of service, whether rendered at the doctor's surgery, in the patient's home, or at a private hospital, commands the same fee (7*s.* 6*d.*); but most practitioners have been in the habit of charging additional fees to patients who seemed able to afford them. Obviously, when it can draw on an unlimited State fund this system is open to abuse: the report speaks of "cases where general practitioners were receiving annual sums much in excess of what could be regarded as reasonable and proper remuneration," and it says that "the present invariable practice of obtaining a certificate from the patient, parent, or guardian as to the dates, &c., of attendance has only limited value." Yet, in spite of these shortcomings, the fee-for-service has become so much a part of the New Zealand way of life that the committee does not seriously contemplate any alternative. Of payment by capitation it remarks that "under the existing circumstances in this country a renewed attempt to introduce such a system generally could not succeed," and that capitation "tends to a decline in the high standard of practice." Oddly enough, the few doctors who accept patients under the capitation scheme mostly operate the fee-for-service too. In the absence of safeguards (and none are mentioned) this seems to offer the unscrupulous the best of both worlds—the good lives contributing their regular capitation income, the bad ones the fees for service. The committee understandably recommends that practitioners should not be allowed to practise under both systems at the same time, but should be obliged to choose between them.

Having dismissed salaries and capitation, the committee considers how fee-for-service remuneration can be reformed and simplified. It proposes to abolish the refund system, and require the practitioner to make all the claims for his payment. But to salve the conscience of those who object to being paid directly by the State—lest this destroy their professional freedom and the doctor-patient relationship —a form of words has been devised to make it clear that the doctor is claiming the moneys not on his own behalf but "on behalf of the patients listed in column (3)." So into column 3 of the claim form must go the names of all the patients (or their legal

Moss, M., Squire, J. R., Topley, E. *Lancet*, 1948, i, 320.
Hobbs, B. C., Carruthers, H. L., Gough, J. *Ibid.* 1947, ii, 572.
Whitwell, G. P. B., Sutherland, I. *Brit. J. industr. Med* 1948, 5, 88.

In the U.S.A. the new hopes for the tuberculous which were based on the first trials in that country, assisted by uncontrolled commercial enterprise and an ever-increasing supply (including eventually sales over the counters of drug stores even without prescription), led to a situation where almost every hospital patient with money, and about 50% of all inpatients, were given the drug at some time—whereas more cautious American physicians estimate that it is medically indicated in about 10%. Indeed it is said in the U.S.A. that if your railway dining-car attendant is unsteady and spills the soup down you, tuberculosis should be suspected! Here a more cautious attitude, together with the dollar shortage, has caused the Government to advance warily. During 1947 and 1948 enough streptomycin was imported for M.R.C. trials, later for official release to hospitals for meningeal or miliary tuberculosis, and still later for ulcerative tuberculosis of the larynx, trachea, and bronchi. Apart from the swelling trickle of individual purchases of American streptomycin, officially tolerated as a safety-valve but of rather doubtful morality, the antibiotic has been unobtainable in this country for pulmonary tuberculosis. Now that home-production has increased substantially, we may expect a wider, though still limited, release from Government internal purchases. Will the wave of indiscriminate use follow the American pattern, or can it be modified by self-discipline? Much will depend on the persuasive guidance given to the doctors entrusted with the drug. It may be wisest to confine distribution to tuberculosis officers and other specialists, with access to laboratory, X-ray, and preferably also hospital facilities; for lack of appreciation of the toxic effects of the drug, failure to test cultures for susceptibility at the beginning, during, and at the end of treatment, and failure to watch progress by X ray under standard conditions, may do harm to the patient besides wasting a valuable drug. No doubt there will be temptation to use streptomycin to treat an early lesion, so as to get the patient back to work quickly; to use it instead of collapse therapy or even bed-rest; and to treat hopeless cases to please relatives. But in the vast majority of cases the physician will have a free hand; he can weigh the advantages and disadvantages of streptomycin and act accordingly. Used with discrimination this remarkable new weapon can successfully supplement the proved methods of attack on a small though important sector of the tuberculosis front. The National Health Service can play its part by seeing that the drug is available at the right place and at the right time.

Epidemiology of Staphylococcal Infections

If measures of preventing and controlling epidemics are to be logically and successfully applied, the sources and paths of spread of epidemic infection must be exactly known. Such knowledge can only be gained when the infecting organism can be accurately defined and identified. Epidemiological studies of the acute streptococcal infections during the last twenty years have given us a valuable body of new information and are an outstanding example of the incentive to research arising from the definition of serological types within a bacterial species. This has only become possible as a result of the differentiation of some thirty serological types of *Streptococcus pyogenes* by the late FREDERICK GRIFFITH. Another example is the phage typing of *Salmonella typhi*, described by CRAIGIE and YEN, which is now being used every day to trace the sources of epidemics and cases of typhoid. More recently the serological differentiation[1] of types among *Staphylococcus pyogenes* and the development of phage typing[2] of that organism have brought the epidemiology of staphylococcal infections into the limelight. An organism so ubiquitous as the staphylococcus does not readily lend itself to epidemiological studies, but the field has been somewhat narrowed by the recognition that coagulase-production will differentiate pathogenic or potentially pathogenic strains from the rest. Type differentiation by serological and phage methods has therefore been applied only to coagulase-positive strains.

The main application of typing to the study of staphylococcal epidemics has been in institutional outbreaks of pemphigus neonatorum. In one outbrea involving 22 infants, ELLIOTT and others[3] conclude that a nurse who was a nasal carrier of the epidem strain had been the source and means of sprea of infection. ALLISON and HOBBS[4] described thr successive outbreaks of pemphigus neonatorum an staphylococcal conjunctivitis involving 132 infan in a large maternity unit, and demonstrated the wid spread occurrence of the epidemic strains in t infants' environment; their evidence pointed to t nurses as the source of infection, with the nas passages as its main reservoir and the hands the probable vehicle of spread. By phage typi ROUNTREE[5] was able to prove cross-infection wi pathogenic staphylococci in 18 out of 82 surgic wounds in a 24-bed surgical ward over a period seventeen weeks. In a study of penicillin-resista strains of staphylococci causing infections in a hospit unit, BARBER[6] showed that of 7 strains isolated fro patients during a single month, 5 penicillin-resista strains all belonged to the same phage and serologi type while 2 penicillin-sensitive strains belonged to different type, and she attributed the infections spread from patient to patient. Similarly in outbrea of staphylococcal food-poisoning due to enterotoxi typing of strains of staphylococci isolated from t suspected foodstuff, from the vomit or stools victims, and from the nose and hands or septic sk lesions of food-handlers has added to our knowled of the sources and modes of infection. Among t many outbreaks successfully traced to their sourc may be mentioned those described by WILLIAMS et al. in which infection of ice-cream was traced to the no and hands of one of the people who prepared i and by ODDY and CLEGG,[8] who showed that an ou break involving 167 miners who had eaten infecte pressed-beef sandwiches was caused by staphyloco isolated from the nose and hands of the butcher wh prepared the pressed beef.

what is known of the tubercle bacillus, it is evident that the conditions necessary for its inactivation will differ from those required for the pneumococcus. Certain experiments indicated that the deleterious effect of 50% humidity on the pneumococcus might be due to increased salt concentration, and similar results have been obtained with influenza virus suspended in a broth containing 5 g. of sodium chloride per litre.[6] (Normal human saliva has only about a tenth of the amount of salt that physiological saline contains.) These American experiments, however, did not include tests with influenza virus suspended in human saliva with and without dialysis, which would give crucial information about the rôle of salt. Edward has suggested that the inactivation of the virus in saliva during drying might be caused by the lysozyme-like agent in the saliva, which might well have a maximum effect at a relative humidity of 50%.

It is obvious that many factors besides humidity play a part in producing an epidemic. But it might be useful to ascertain whether maintenance of the relative humidity at a high level will control the spread of influenza in a closed community.

TRACE ELEMENT PIONEERS

In 1937, when Bennetts and Chapman [7] established that copper deficiency was the cause of enzootic ataxia in Western Australia, not much was known about trace elements in nutrition. The subsequent advances in this field must largely be ascribed to the stimulus applied by the successes of these and other pioneers.

In 1928, after a long series of studies, Hart and his colleagues [8] at the University of Wisconsin had shown that copper as well as iron was essential for the formation of hæmoglobin in the rat, but it was not until 1933 that a disease of economic importance was shown to be due to copper deficiency. This was "liksucht," a wasting disease of cattle in Holland which Sjollema [9] cured with copper sulphate. The enzootic ataxia on which Bennetts and his associates did their classic work is a demyelinating disease of the unborn or unweaned lamb, producing a typical degeneration in the spinal cord which is responsible for the ataxia, usually affecting the hind limbs only. Nutritional disturbances as a rule precede and almost invariably accompany the ataxia. From 1932 onwards, on chemical, clinical, and pathological data, Bennetts [10] built up a working hypothesis that the disease was due to lead poisoning. In his first trials, ammonium chloride, as a "deleading" agent, was fed to gestating ewes and gave very satisfactory results. In a later season the results were inconsistent and it was found that a very pure sample of ammonium chloride did not prevent the ataxia. A spectrographic study of the effective and ineffective samples of ammonium chloride and of livers from affected and normal lambs disposed of the lead hypothesis and suggested that copper deficiency was a more probable cause of the disease. In the next lambing season the administration of copper to the gestating ewe was found to prevent ataxia in the lamb. This was a discovery of major importance to the Australian sheep industry, and, coupled with his prevention of "falling disease" in cattle with copper supplements,[11] has earned for Dr. Bennetts and the Western Australian department of agriculture world-wide appreciation.

Another important early success in trace-element therapeutics, also achieved in Australia, was that of E. J. Underwood and J. F. Filmer. They were investigating a fatal disease of sheep and cattle in localised areas of Western Australia, for which Filmer [12] suggested the name "enzootic marasmus," the principal symptoms being progressive emaciation and anæmia. The disease had been prevented by the administration of limonite ($Fe_2O_3H_2O$) and was thought to be due to iron deficiency. Analysis of the pastures and of organs of affected animals, and finally the prevention of the disease with an almost iron-free extract of limonite, showed that this hypothesis was wrong.[13] By a series of fractionations of this extract Filmer and Underwood [14] finally traced the curative property to cobalt, which invariably checked both the wasting and the anæmia. It is interesting to note that Lester Smith and the American group working on the anti-pernicious-anæmia factor of liver agree that the factor contains cobalt.[15]

DETAILS ABOUT ISOTOPE SUPPLIES

In their statement published in our issue of Sept. 18 (p. 469) the Medical Research Council gave details of the conditions under which radioactive isotopes can now be obtained for research and therapy. Radioactive isotopes require very careful handling by special techniques not normally part of laboratory methods, and with these difficulties in mind the M.R.C. pointed out that stable isotopes of some useful elements were available for tracer research which could be used without any of the protective measures needed for radioactive isotopes. But the estimation of stable isotopes has to be done with a mass spectrometer, a complicated instrument costing about £2000 and calling for more technical knowledge than most medical workers possess.

The Ministry of Supply have now circulated some further information about the obtainable radioactive isotopes and also about stable isotopes and their estimation. At present the Atomic Energy Research Establishment at Harwell is working with a low-energy pile whose usefulness, so far as medically interesting isotopes are concerned, is limited. A larger pile is being constructed, and when in operation (no likely date is mentioned) it will produce isotopes of specifications similar to those now provided by the U.S. Atomic Energy Commission. The low-energy pile has been used to produce radiosodium(Na^{24}), radiopotassium(K^{42}), and radiobromine (Br^{82}). These isotopes are useful in biological research, and since they have half-lives of only a few hours they cannot be imported. The low-energy pile has also produced some radiophosphorus(P^{32}) and radio-iodine (I^{131}) pure enough for use in therapy, but the amounts are too small to be of practical value. When the large pile is operating at full power it will provide these and other isotopes in quantities sufficient to meet all expected demands for scientific and industrial, as well as medical, uses. In the meantime isotopes are being imported, mainly from the U.S.A., and supplies are necessarily limited to the longer-lived isotopes like radio-iron (Fe^{59}, half-life 47 days) and radiophosphorus (half-life 14 days).

The stable isotopes now obtainable are those of nitrogen(N^{15}), carbon(C^{13}), and oxygen(O^{18}). The nitrogen and carbon isotopes have been imported from America, but both will soon be manufactured in this country. The Genatosan Co. at Loughborough is making an enriched N^{15} on a commercial scale. At Harwell a plant for the production of C^{13} is nearing completion, and one for the production of O^{18} will be ready in about three months' time. These stable isotopes are therefore likely to be fairly plentiful before long. With regard to estimation, there are two mass spectrometers at the guardians if they are minors); in column 2 a code letter or letters indicates the service given; column 6 shows the money claimed from the State; while column 5 gives the total amount the doctor intends shall be paid for his services by State and patient combined. To regularise the recovery of fees from the patient the report asks that "every general medical practitioner should have the right to charge and recover a fee additional to that payable from the Fund wherever circumstances, in his opinion, warranted it."

Since the patient is no longer to be asked to sign the claim form, it is recognised that some alternative method of checking the claims made by practitioners is necessary.

> "It is accordingly suggested that the Department devise a system of verification of service as an alternative to the patients' certification, as, for example, postal inquiry from a proportion of the patients of each practitioner. In addition, it is recommended that all practitioners be required to maintain adequate medical records of their patients in support of all claims made, and that these records and daily diary sheets be subject to inspection by medical practitioners duly appointed for that purpose."

But it looks as though the committee doubts whether these methods of sample and scrutiny will be really effective; for later we are told that it

> "discussed the practicability of prescribing limits to the numbers of patients to be seen daily or, alternatively, of prescribing a limit to the amount payable from the Fund to an individual practitioner. It considered that, in view of the wide variation in local conditions, types of patients, and the capacity of practitioners no fixed or arbitrary limits could be prescribed. Nevertheless, there are substantial grounds for believing that an average of, say, thirty attendances [items of service] daily is the maximum number practicable for an efficient and conscientious practitioner, and the Committee considers that Local Investigating Committees [consisting of local doctors with a medical officer of the health department] should be vigilant to investigate cases which habitually exceed the figure mentioned."

As it appears from the other side of the world, this system which our colleagues in New Zealand are arranging for themselves is by no means attractive. If the Minister of Health here were to propose such a combination of snooping and sanctions he would be felt to have exceeded all reasonable bounds. Moreover, the object of the new plan is to support a method of payment which New Zealanders themselves admit does not encourage good medicine. In his presidential address this year Mr. J. A. JENKINS, president of the N.Z. branch of the B.M.A., said: "It is the quality of the medical service that should count, not the quantity. The present system pays premiums for quantity and penalises care, thought, and time spent. This is basically wrong." But even he could see no alternative to the fee-for-service —"the salaried service, the capitation system, in fact anything that departs from what is ingrained in us is bound to fail"—and he based his hopes on placing administration in the hands of a permanent, predominantly medical, corporate body, and on the levying of additional fees for every conceivable item the patient needs. He believed that "if the government . . . placed a small financial barrier between patient and doctor, patient and chemist, and patient and hospital, many of the present abuses would cease at once." Would they? We wonder. But th we have never had quite the same dislike (in princip of capitation fees, nor the same faith in the fee-f service. In the next year or two this country w have to find whether a capitation system embraci the whole population is compatible with high standa of practice. Meanwhile, if the New Zealand gove ment accept their committee's recommendatio New Zealand will be ascertaining whether the adm tedly unsatisfactory trends of her practitioner serv can be reversed by altering the method of claimi fees.

Annotations

THE ACT IN ACTION

UNDER this title we propose to publish a short se of occasional articles on the working of the Natio Health Service during its first few months. They w describe some of the difficulties encountered and so of the defects observed. Signs of strain can be instructi even when they appear in the less vital parts of organism, and we shall begin by examining one or t of the most conspicuous. The opening article de with the supply of spectacles.

HUMIDITY AND INFLUENZA VIRUS

IT is now recognised that the most satisfactory mea of preserving most viruses is to dry them in va from the frozen state. By this method the virus rapidly desiccated past the presumed critical degree moisture at which its susceptibility to external influen is greatest. Similarly, it has been shown that smallp virus, in infected crusts or in vesicle fluid dried on gl slides at room temperature (22°C),[1] and foot-and-mo virus in cattle saliva, will survive and remain infecti for periods of several weeks to a year or more (smallp crusts) under natural conditions. According to S Leonard Rogers,[2] these findings support his oft-repeate argument that the spread and prevalence of smallpo is least at periods of high relative humidity of th atmosphere.

In exploring the epidemiology of influenza, a numb of attempts have been made to estimate the survival the virus under more or less natural conditions. F example, Edward[3] showed that when a 5% suspensi of infected mouse lung in normal human saliva w allowed to dry on glass slides at room temperatu only 1% of the virus could be recovered when dryi was complete. He also found that when pieces of she were impregnated with a given quantity of mouse-lu virus, and the virus was allowed to dry under differe conditions, much less virus was recovered when dryi was slow because the humidity of the atmosphere w high. Loosli et al.,[4] in Chicago, demonstrated th influenza virus dispersed into the air is killed mu more swiftly in humid than in dry air, and it has no been shown[5] that when pneumococci type 1, suspende in broth, saliva, or 0·5% saliva, are sprayed into th atmosphere, their mortality is very high at relati humidities in the vicinity of 50%. (At humidities abo or below this value they survived for long period

Though a similar type of pattern was obtained wit staphylococci, the results were not nearly so strikin which makes it probable that the effect of humidit depends on the structure of the micro-organism. Fro

The Act in Action

1. SPECTACLES

BEFORE the start of the new National Health Service, the output of spectacles from all sources was 4–5 million pairs a year. Representatives of the ophthalmic industry place the present demand at over 650,000 pairs a month (7,800,000 a year). The demand is growing, and the delay in fulfilling orders—which is now from four to eight or more weeks—is also growing, according to the industry, by one week for each week that passes.

The eventual aim is to base all ophthalmic services on hospitals. Meanwhile patients who are not already attending hospital are dealt with under the Supplementary Ophthalmic Services. The original estimate of the cost of these services in England and Wales from July 5 to the end of next March was £2,080,000: the actual amount spent in the $12^1/_2$ weeks up to Sept. 30 was £981,951. Before having his eyes tested, the applicant must obtain from his own doctor a recommendation for examination, written on a form which he takes either to an "ophthalmic medical practitioner" (who draws £1 11*s.* 6*d.* for testing the vision), or to an ophthalmic optician (who receives 15*s.* 6*d.* for his service). If glasses are necessary, the prescription is sent to the local ophthalmic services committee, which, if it approves, returns the prescription to the patient, who then takes it to an ophthalmic or dispensing optician (to whom a dispensing fee of £1 5*s.* is paid). With the present urgent demand fees are mounting up; and the general practitioner is ruefully comparing the capitation fee he gets for a year's service to a patient with the sum—about double—received by the ophthalmic practitioner for a single test of vision. In the school ophthalmic service, at present administered under the supplementary services, the amount earned on capitation fees has certainly sometimes exceeded reasonable need. Hence the school service is to be placed under the hospital board by the end of next March; and until then payment is to be made on a sessional basis.

The approximate numbers operating the service in England and Wales are as follows [1]: ophthalmic medical practitioners 1126, ophthalmic opticians 5821, and dispensing opticians 620. The patient who applies for examination may find that he has to wait from a week up to a month or longer to have his vision tested by an ophthalmic medical practitioner or optician. To this delay must be added the time taken by the executive council's committee to approve the prescription. This was at first as long as a month in some districts, but it has been reduced, except in one area, to a few days; and it is eliminated altogether by friendly opticians who proceed with the order on the assumption that approval will be given. Thus the time between the date of fixing an appointment and the issue of spectacles is at best about 4 weeks and at worst some 3 months.

PRESENT AND FUTURE

It is easy to understand how the present acute demand originates. First of all, there are those who, though needing spectacles, have never before had them made; some idea of their number is given by the popularity of ready-made spectacles before the war, when a single group of chain stores is reputed to have sold 2 million pairs a year. A second group is composed of people who, having a pair of spectacles, seek a re-test; according to one estimate these form 80% of all applicants. Indeed, at least one ophthalmologist, having entered the service and doubled the time given to refractions, finds that he can see only patients who attended him before July 5. In most cases the claim is reasonable because vision was last tested some years ago. Sometimes less reasonable are the claims of the men and women, from all walks of life, who, ignoring the fact that their actual contribution is never more than 10*d.* a week, announce an intention "to get something back for the £12 a year I pay for medical service." This group seeks a tangible return, often in the form of spectacles, for what is considered an unreasonable outlay. A less querulous section hopes for examination simply because the service is free. Yet by general agreement the proportion of applicants not in need of spectacles is no more than 10%. An optician in East London who surveyed the first few hundred patients examined under the scheme has reported [2] that 19% of these patients were wearing glasses for which they had never been examined; 47%, already with glasses, had not been re-examined during the past 4–10 years; and only $16^1/_2$% had never worn glasses before.

THE INDUSTRY'S CRITICISMS

The popularity of the new ophthalmic service was partly foreshadowed by a drop in the sale of spectacles from last January onwards; and the ophthalmic industry claims that if, in the months before the service started, it had been given a chance to prepare stocks according to the scales eventually laid down, present difficulties could have been largely avoided. As it was, the scales were made known only in June. The official scales schedule 19 types of frame to be provided under the scheme —10 to be issued free and 9 on payment of a supplement. If an optician stocks a dozen of each type in two sizes, he will have altogether 38 dozen. This, some opticians reason, is extravagantly many; and the range might be reduced. Nevertheless, despite temporary shortages of one or two types, manufacturers' capacity equals the present demand; and no doubt production, especially of the 7 plastic types which are listed, could be stepped up without great delay.

The position with regard to lenses is far less happy, accounting as it does for almost the whole delay in manufacture. Output is restricted both by the number of skilled workers—for lens-making is a craftsman's job —and by the shortage of machinery for grinding; and there can be no substantial increase in less than two years. In the meantime, some manufacturers believe that speedier service could be assured by reducing the types of lenses. Criticism is directed particularly to the issue of toric lenses without charge "for distant and/or constant wear and for reading when prescribed as being necessary," or otherwise on payment of a supplement. It is pointed out that only 4 such lenses can be produced in the time taken to produce 36 flat lenses.

Unfortunately, for present purposes, the industry was geared to increased production of flat lenses in the war, to meet Service orders; in most other countries only toric lenses are now used. The Ministry of Health says that had only "utility" frames been provided the results would have been (1) to cause a great demand for such frames, leading to even greater delay, (2) to make more people get their glasses privately, thus defeating the objects of the service, and (3) to discourage people needing glasses from getting them. The aim has been to set up a good, popular service—"not a utility one to which public opinion would have been justifiably opposed." If the productive capacity for flat lenses was not being fully used, the position with regard to toric lenses, says the Ministry, would be reviewed.

OTHER ASPECTS

Doctors and opticians sometimes argue—in opposition to the spirit of the Act—that if the patient is to value his spectacles, he must pay all or part of their cost. On the other hand, the service is evidently fully appreciated

2. *Dioptric News*, 1948, 3, 357.

National Institute for Medical Research, Hampstead, N.W.3, which can be used for assaying samples for research-workers, and the institute will advise on the preparation of samples of blood and other biological materials. Gas samples can be dealt with at Harwell, but so far only to a limited extent.

Some useful addresses are given in the Ministry of Supply's circular. Inquiries about radioactive and stable isotopes should be addressed to the Isotope Information Office, Atomic Energy Research Establishment, Harwell, near Didcot, Berks. Departments and individual research-workers who propose to use either form of isotope for medical research should apply to the secretary, Medical Research Council, 38, Old Queen Street, London, S.W.1. Short-lived isotopes will be distributed direct from Harwell. Isotopes that have to be processed before issue will be sent out from the Radiochemical Centre at Amersham, Bucks.

THE LAW AND INSEMINATION

In the opinion of Mr. Justice Vaisey and Mr. H. U. Willink, K.C., given in the report of the Archbishop of Canterbury's commission,[1] artificial insemination with donor's semen (A.I.D.) constitutes adultery; and this opinion was shared by eleven out of the twelve members of the commission. Mr. Cecil Binney, addressing the Eugenics Society on Oct. 26, took a different view. The law defines adultery, he said, as any sexual act between any two persons of opposite sexes, one of whom is married. In short, some degree of concupiscence must be present; whereas with A.I.D. concupiscence is wholly absent. He thinks it unlikely in any case that suits dealing with artificial insemination will often appear in the courts. Where the husband's semen is used (A.I.H.) no legal complications arise; and he does not agree that such cases might be affected by the Law of Nullity, since a nullity suit can be successful even where the wife has had a child by the husband. Donor insemination, on the other hand, might conceivably give rise to complications under the Criminal Law, the Law of Divorce, and the Laws of Inheritance. The donor has no reason to fear that his behaviour is illegal, since any man can inseminate the wife of another without committing a legal crime; and though the majority of the Archbishop's commission wished A.I.D. to be made a criminal offence, Mr. Binney thinks it is unlikely that this will be done, since it would encourage perjury and blackmail. He contended that no special provision is needed for the case of the wife who has herself inseminated without her husband's knowledge, since a husband could almost certainly divorce her, if he wished, on grounds of cruelty; while the wicked doctor who inseminates a woman against her will, or the adventuress who has herself inseminated so as to make unjust claims on some man, are figures of fiction rather than ordinary life.

Nevertheless, some possible complications do need study. The child is not the husband's, and strictly speaking the mother ought to register it as illegitimate. In practice, however, Mr. Binney pointed out, a married man can accept as his own any child of his wife's, and can make what provision he likes for it in his will. Troubles are more likely to arise when there are entailed properties or funds in trust. Mr. Binney would meet this objection, given his way, by the abolition of entail and settled funds; but he sees no hope of such a solution.

The danger of incest as a result of two A.I.D. children growing up and marrying he considers small—probably not greater than the danger, always present, of any two unknowingly related people marrying. In village communities, and in small communities of English peop living abroad, this is always a possibility, though n one which gives rise to much anxiety. There remai the suggestion that civil proceedings might be tak against the doctor; but this could hardly happen whe husband and wife had authorised the operation. the husband had not been informed, he might, on t curious legal ground that the doctor had interfer with his wife's services to him, take action. This wou be akin to a father getting damages when his daught is seduced. A claim against the doctor could, of cours be made if the operation was unskilfully or negligent done, or if the child turned out to have some heredita disorder or abnormality; or an awkward situatio might arise if a doctor who disbelieved in racial prejudi provided an insular type of woman with a child of noticeably different race.

Mr. Binney evidently felt that though the subje makes a fascinating playground for lawyers, the practi of artificial insemination—even of A.I.D.—on the existin minute scale is likely to give very little trouble to anyon

THE DONORA DISASTER

During the last five days of October a large part western Pennsylvania was covered by a fog blanke and at the steel-making town of Donora 18 elderl patients with asthma or with heart disease died in o day, and about 200 persons came under treatment f the alleged effects of "smog" (smoke and fog). T town hospital became overcrowded, and an emergen hospital was set up. A zinc-smelting plant was closed

The connexion of fog with an increased mortali from respiratory diseases was demonstrated on a statistic basis by Russell, who pointed out that fog alone h apparently no effect; it has to be associated with co weather to make it lethal.[2] He even claimed th "knowing the temperature and the amount of fog, it possible to predict the mortality of the succeeding wee but only with a marginal error of roughly 30%."[3] T question how much of this increased mortality is d to fog, and how much to cold has been discussed b Woods.[4] At Donora, however, it is plain that other factors have been at work. We know that fog produced by an earth-bound layer of cold air prevents factor fumes from rising into the upper air, and it was in th sort of weather, at the beginning of December, 1930 that 63 people died of respiratory disease, within a perio of little more than twenty-four hours, in the Meus valley, in an area 25 by 1–2 km., south of Liège. The deaths there were attributed to atmospheric pollutio with sulphur dioxide and hydrofluoric acid by zinc an superphosphate factories. So extensive had been th pollution that the soil had been rendered useless fo agriculture and spoilt for grazing, and breeders of cattl had obtained damages against the manufacturers. Th fact that electric-light bulbs lost their transparency quicker there than elsewhere points to fluorine as th guilty agent. Of the 27 factories 15 used fluorine containing substances.[6]

The dangers of fluorine have been clearly described, and closure of the zinc-smelting plant at Donora was amply justified by the known facts.

It was announced at Stockholm on Oct. 28 that the Nobel prize for medicine is to be awarded to Dr. PAUL MOELLER of Basle for "his discovery of the effects as an insecticide of D.D.T."

ORGANISATION

Income from all sources is pooled and distributed among the partners in accordance with an agreed plan, laid down in the partnership agreement and subject to modification with the passage of time. The division is assessed mainly on two factors: (1) age and seniority in the group; and (2) the recognised higher earning capacity of surgeon-specialists. The government and administration of the group is entirely democratic, decisions being reached either unanimously or by a wise compromise.

The central office of the group is the ground floor of a large residential house, equipped to provide four sets of consulting-rooms, physiotherapy-room and minor-operations' theatre, general waiting-room, dispensary, and offices. There is also a dark-room for eye and ear work. The first floor of the house provides a residential flat for one partner. All the firm's consulting is done from these premises. The property and equipment is owned jointly by the partners. To prevent standardisation, each partner furnishes his own consulting-room and is responsible for its decoration.

Each member of the group is on the honorary medical staff of the local hospital, which has 50 beds and an elected medical staff. The surgeons and physician each hold outpatient clinics at the hospital. The group keep close touch, both in their private and hospital practices. Apart from formal consultations, arranged at the patient's request, members of the group assist each other in cases of difficulty, without additional cost to the patient. Problems of current interest are continually discussed. The group meets regularly to discuss administrative problems, but hitherto pressure of work has made it impossible to arrange clinical discussion on a formal basis.

Non-medical duties are divided between the partners. These include supervision of staff and finance, supervision of dispensary and ordering of drugs, supervision and [illegible] of instruments, &c., and upkeep of fabric of premises.

The non-medical staff comprises a secretary book-keeper, a part-time shorthand-typist, a dispenser, a receptionist, and a part-time cleaner. The secretary is in a key position, holds great responsibility, and is well paid. The dispenser is "Apothecaries' Hall trained." Wages of the staff amount to £900 p.a., of which the secretary is paid £343 and the dispenser £312. This is not an excessive outlay for a partnership of five doctors. The willingness, interest, keenness, and efficiency of the staff is considered of vital importance. The principle of offloading unskilled work and non-medical administration as far as possible from the partners, as a long-sighted economy, is carefully pursued. Auxiliary help more than pays for itself, by freeing the partners for purely medical work.

DOCTOR-PATIENT RELATIONSHIP

The preservation of the doctor-patient relationship is considered to be an ethical principle of the highest importance to be maintained at all costs. For this purpose, patients are not encouraged to transfer from one partner to another within the group, unless there are special considerations such as transfer of cases from a partner who is so overworked that he cannot cope with his present work, or transfer of a special case to a partner specially experienced in that department—e.g., a difficult diabetic from surgeon to physician, or a difficult surgical case from physician to surgeon.

When another partner treats a patient of a member of the group for a special service, the patient is returned to the original doctor when the service has been completed. If the patient definitely desires to change to another member of the group, he is of course free to do so. No difficulties between partners have arisen for this cause. It has not been found that the service so given has become impersonal, or that the members have sought to pass the responsibility for their patients to the group as a whole. Personal responsibility of one doctor for each patient and free choice of doctor are maintained. When a consultant is required for an opinion or an operation, the patient is free to choose any specialist, inside or outside the group, and no pressure is applied to influence his choice. The group emphasises the place of the family doctor as the key man, directing and coordinating treatment.

SCOPE OF SERVICE OFFERED

The scope of the group is adapted to the needs of the district. It is limited in this area by (1) shortage of hospital-bed accommodation, excluding accommodation for such specialties as ear, nose, and throat work (except tonsil operations) and ophthalmic cases; and (2) the comparatively small size of the area served, which limits the group to the major specialties. The group's service is at present confined to general medical, surgical, gynæcological, and obstetric work, with provision of consultant service in each department, modern anæsthesia for all cases, and facilities for some highly technical procedures which are not always available outside the special departments of big hospitals. Raising the standards of general medical practice within the group is considered as *important as providing additional facilities for treatment.*

X-ray, pathological, and orthopædic services, as well as the minor specialties, are provided by the local hospital, or by a large non-teaching hospital 15 miles away. No gross inconvenience is caused either to the partners or to patients by the fact that these services are not available within the group.

PHYSIOTHERAPY

Physiotherapy for private patients had been inadequate in the area until the group introduced a physiotherapist. Though the group could finance, accommodate, and use a full-time physiotherapist, it was thought undesirable and unethical to restrict her services to doctors or patients of the group, and she now works in exactly the same way as any other masseuse in private practice, except that she uses the group's clinic for her headquarters and consulting-rooms. To attain close liaison with practitioners outside the group, she is willing to treat patients in other doctors' consulting-rooms, if the necessary apparatus is provided.

In the difficult post-war economic conditions it was clear that no physiotherapist would set up in private practice in this area without being sponsored. That an efficient and keen masseuse is now in active practice in the area is looked on as yet another advantage to the population of the area, whether they are patients of the group or not.

RELATIONS WITH MEDICAL PRACTICE OUTSIDE THE GROUP

The local hospital forms an integral part of the life of the group. Of seven members of the "limited" honorary medical staff five belong to the group. At an early stage it was realised that an efficient hospital was essential to the group (just as the efficiency of the group was essential to the hospital), and later members of the group were chosen with this principle in mind.

The group has two equally important spheres of activity and cooperation—its own consulting-rooms and the hospital. Close contact is maintained between members of the group in their hospital work, surgeons advising on surgical aspects of medical cases, and the physician being available for preoperative examination of operation cases and for advice on postoperative treatment. Without the hospital the group would not have by wives (who may hitherto have unselfishly foregone their claim) and by old people.[3]

Among the wealthier patients a few go to great lengths in trying to obtain through the service spectacles prescribed by a private ophthalmologist of their own choosing. Otherwise there seems to be singularly little abuse by the patient. Indeed, abuse is made very difficult by the triple check enforced by the family doctor, the ophthalmic practitioner or optician, and the executive council's ophthalmic committee. But if there is little abuse, there is equally little inclination to pay for extra service. Among opticians private practice has almost ceased, and now accounts for only about 4% of all work; and an optician in the heart of a very wealthy urban area reports that of 300 people supplied with spectacles under the scheme only 4 have opted for one of the varieties on which a supplement is payable.

There have of course been mistakes and difficulties in administration. Ophthalmologists complain that practitioners sometimes misuse the form recommending test of vision to refer a patient who should properly go to hospital. An ophthalmologist who takes a school clinic is irritated by the experience of being unable to obtain non-splinterable lenses for children at the clinic.

Opticians, for their part, observe with some anxie that payment is slow in reaching them. These a mostly passing annoyances. The one formidable dif culty is in the supply of lenses.

Doctor, optician, and patient are at one in reasoni that no ophthalmic service can be truly efficient so lo as the delay in supply is a month or longer. Amo the ways in which delay could possibly be curtailed these:

1. *Eventual increase in production of lenses.*
2. Limitation in the types of lenses.
3. Restriction of the service to the patients most urgen needing spectacles—e.g., for work or reading.
4. *Propaganda urging temperate use of the service.*

None of these courses, except the first and perhaps t last, is likely to find general support. To the cru question of how soon and at what level demand settle there is still no firm answer. Mr. G. H. Gil secretary of the British Optical Association, belie that 40% of the population require an aid to visio that a fifth of this proportion still have no suita spectacles; and that the eventual demand from whole of Great Britain will be in the neighbourhood 7 million pairs of spectacles a year, costing about million.

A MEDICAL GROUP PRACTICE

Two Years' Experience

A REPORT FROM THE GROUP

THE experiment outlined here is constitutionally English in nature—that is, it has developed freely and naturally in response to local needs without any outside pressure or copying of any model. It is capable of infinite adaptation according to the locality. No attempt has been made to provide a complete medical service. Its function is mainly to complement the medical service in the neighbourhood and to provide treatment, otherwise obtainable only at a distance, in the patient's home town by the doctors who know his particular needs.

The group under consideration was formed in 1945 by the fusion of two old-established medical practices, each previously containing two partners. The motives which led to its formation were:

(*a*) To provide a comprehensive medical service for the patient in his own locality and within his financial means, by increasing the scope of domiciliary and hospital treatment.

(*b*) To increase the scope of each member of the group by providing him with greater experience in his own specialty and thus to increase his competence and skill.

(*c*) To raise the standard of professional skill by mutual consultation.

An illustration will make the first motive clear. A small "group" of two—specialist surgeon and specialist physician—cannot undertake dissection of tonsils without the aid of the special skill of a specially trained anæsthetist. It was therefore necessary to introduce an anæsthetic specialist into the group, and the surgical scope of the practice was thus widened.

The group works in a country town of 10,000 population, the surrounding countryside containing a further 15,000. The area has a radius of 8–10 miles. Two other doctors practise in partnership in the town. The nearest large centre of population is a city 15 miles away. The group is composed of a surgeon-obstetrician (F.R.C.S.E.), a physician (M.D., M.R.C.P.), an anæsthetist (M.B., D.A.), an assistant anæsthetist (M.B.), and a second surgeon (F.R.C.S.E.). The five members of the group all have specialist experience, four out of five having served in late war as specialists in the Services; four out of are members of the B.M.A. part-time consultants r

All members of the group undertake general practi all, except the senior partner, undertook N.H.I. w The physician does no midwifery. Members retain th own patients, but there is close intermingling. E partner has a recognised deputy, who stands by for and is introduced to his patients as far as possi The anæsthetist gives all the surgeon's anæsthetics the set operating lists, irrespective of the nature of operation, and either he or the assistant anæsthe gives anæsthetics for all but minor emergencies. T casual or occasional anæsthetist is thus eliminated. T two surgeons assist each other at all set operations benefiting by each other's experience and shortenin duration of the operation. The second anæsthet specially trained in transfusion technique and acts blood-transfusionist to the team.

The following is an example of the group's cooperati and organisation:

A patient was referred to the surgeon as a hospital o patient diagnosed as having carcinoma of the cæcum and la admitted to hospital for resection of bowel. He was se by the group physician for assessment before operatio It having been decided that the procedure was well with the capacity of the group, the operation was performed by t first surgeon, assisted by the second surgeon; the anæsthet (thiopentone, cyclopropane, and curare) was administe by the first anæsthetist, with the second anæsthetist standi by ready for blood-transfusion if required. Thus all fi partners in the group were intimately concerned in t management of one surgical case.

The organisation of the group fits closely into th definition laid down by the American Group Practic Council:

> "In order to be considered a medical group practic unit, an association of physicians of different skills, usin medical equipment and nursing, technical and admini strative personnel in common, must have a formal patter of professional collaboration, a definite relationship as group with a hospital or hospitals in the community an a unified administrative and financial organisation."

Using American terminology, this is a service group consisting of general-practitioner specialists, with an added "reference" function in which manner it is used by the practitioners of the outlying villages.

The success of this group has been built on complete dom of action as a group, and on the much-discussed onal profit motive. How greatly it will be affected restrictions imposed on part-time consultants prac- ing in groups, where some members have G.P. contracts h local executive councils, remains to be seen. Any ial attitude which prejudices the free action of the eral practitioner consultant is likely to be fatal to dical group practice.

CONCLUSION

Though reference has been made to the P.E.P. broad- et *Medical Group Practice in the U.S.*, it should be arly understood that the conclusions reached by this glish group were independent of any outside experi- e, and that the group developed out of the individual perience of two of its members, without any contact h, or experience of, other such groups in the United gdom or abroad. This report was, in fact, prepared fore the P.E.P. broadsheet was published, but it was equently rewritten to comment on some aspects of up practice emphasised by American exponents, h whose experience this group is in remarkable cord.

SUMMARY

A highly successful experience of two years in group actice is discussed.

The group comprises a physician, two surgeons, gynæcologist-obstetrician, two anæsthetists, and a ysiotherapist.

Each member undertakes general practice as well as own specialty.

The group works on a basis of planned coöperation, finances being pooled and distributed on an agreed

The advantages of the group practice as distinct from e of individual practices and financial combines are cribed.

disadvantages have been found in this group ce.

NEW ZEALAND MEDICAL SERVICES

FROM A NEW ZEALAND CORRESPONDENT

SELF-CRITICISM is not one of the more obvious qualities the New Zealander. Indeed a distinguished visitor has ently accused us of smugness. So perhaps as regards State medical scheme one would not expect the doctors be very vocal in criticising the goose that lays the lden eggs. After all they are 7*s.* 6*d.* ones, even if it a goose that lays them. But criticism has been more pparent lately, even to discussion in the House of presentatives; and now we have the report of a mmittee, consisting of officers of the department of alth and representatives of the British Medical Asso- ation, set up last October to examine the medical ovisions of the Social Security Act and their admini- ration, and to advise what alterations are needed to e effect to the government's policy of making available equate and proper medical services (general and cialist) free or substantially free of cost.[1]

New Zealand has hitherto had no disciplinary body cept the Medical Council, which corresponds to the eneral Medical Council. There has been nothing alogous to a panel committee, and nothing to main- ain ethical standards above the level of "infamous" behaviour. There was indeed provision in the Act and its regulations for the establishment of such committees; but, with the medical profession unwilling partners in the operation of the system, nothing came of them. The new report now agrees to the need for disciplinary bodies, and suggests that they should be set up at two levels. There should be a local investigating committee for each health district to hear complaints against doctors and to investigate allegations of over-prescribing. If it finds that there is a case to answer it is to refer it to a disciplinary committee which would have power to deal with all complaints not serious enough for the Medical Council—presumably on the same basis of fines up to £50 as the original Act provided. There is also to be a General Advisory Committee, recognised by the Minister as the chief consultative body in all matters affecting medical services.

In considering general-practitioner services the committee were satisfied that in some cases doctors were receiving annual sums much in excess of what could be regarded as reasonable remuneration. As a check on this they suggest that 30 patients a day is as much as a doctor can do justice to, and that where he habitually exceeds this number he be invited to meet the local investigating committee. But they do not favour a change from the fee-for-service system, a great merit of which, from the doctor's point of view, is that it leaves him free to accept or refuse a call as he wishes. Some changes are suggested in the payments. An extra 2*s.* 6*d.* is advocated for home visits, so as to discourage large surgery attendances and to bring the system into line with the custom, already common, of making an extra charge for going out. Telephone consultations should be paid for at a rate up to 5*s.* in rural areas approved by the medical officer of health. Where the only service is to repeat a prescription no payment should be made—a recommendation in which the committee show a certain naïveté: what happens if the doctor *looks at the patient's tongue?* Finally it is suggested that the doctor's right to recover fees at law should be restored, provided that the patient is given a month in which to refer the matter to the local investigating committee.

Hitherto specialist services have not been covered by social security, and the only contribution the patient could get was the 7*s.* 6*d.* standard fee. The committee think that specialists should now be brought into the scheme, and suggest that for their recognition, which would need legislation, there should be four requirements—adequate training, a higher qualification, hospital experience, and recognition by the applicant's colleagues. Most specialists will have to be part-timers, and the committee advocate the system under which hospital staffs are chosen from local doctors, instead of being purely internal, as a means of increasing their number. Many knotty problems are left for future consideration, including most of those concerned with remuneration: but they suggest that the contribution for a consultation, for which the usual fee is £2 2*s.*, should not be more than £1 10*s.* In any case the fund is going to be landed in further heavy commitments, and any decision as to the introduction of specialist benefits must take seriously into account the financial obligations involved.

The heavy, indeed enormous, cost of drugs has long been the subject of apprehension. Something has got to be done about it, and the committee suggest two approaches. The public ought to pay at least a proportion of the cost, except in cases like the supply of insulin: and the doctors should work to a revised formulary, with the possibility of appearing before the local investigating committee as a deterrent against over-prescribing.

Drastic changes are suggested in the method of paying general practitioners from the fund. In the first place it should be for the doctor to make the claim, thus eliminating the present alternative by which the doctor charges his fee and leaves the patient to recover 7*s.* 6*d.* from the fund. Secondly, the individual certificates signed by each patient after he has seen the doctor, which now serve as the authority for payment, should come into being, and the group is wrapped up with its future.

---

[1] A summary of the report, from our regular New Zealand correspondent, appeared on Oct. 2 (p. 545).

All routine general surgical and gynæcological operations and abnormal obstetric cases are undertaken, except the more uncommon and the most extensive, which are passed on to specialists with greater experience of these departments. Thoracic and cerebral operations and the more specialised orthopædic procedures are not undertaken, since the function of the group and this *hospital is not to compete*, but to coöperate, with other hospitals and to do all straightforward operations and investigations sent in by surrounding doctors. The surgeons and physicians hold weekly sessions for outpatients.

Close liaison with the nearest non-teaching hospital is maintained. Members of the group pay weekly or occasional visits to the hospital departments, both inpatient and outpatient. It is hoped that this will develop into their official recognition as clinical assistants to the consultants of the larger hospital. Until recently the *principal limiting factor* in this advance has been shortage of time of group members.

Many local practitioners refer cases to members of the group for specialist opinions, whether in hospital, at the group consulting-rooms, or at the patient's home. Besides this, two members of the group have been instrumental in forming a medicochirurgical society, of which all doctors in the town and countryside are members. This society has proved of the utmost value professionally, socially, and medicopolitically.

ADVANTAGES OF GROUP PRACTICE

The advantages, to doctors and patients, accruing from *any form of medical combine* can be divided into those particular to group practice (using the term in the "team" sense) and those common to all forms of medical partnership, including those combines which are financial only. The advantages of the latter include reduction in overhead charges, such as rent and service in joint consulting-rooms, the provision of additional secretarial help (which, perhaps, a practitioner in solitary practice could not afford), and mutual assistance with off-duty and holiday periods, eliminating the need for a locum tenens. These advantages represent a great financial saving to doctors working in partnership.

The advantages obtained from group practice are not, however, of a financial kind. It is doubtful if there is any direct material gain from group practice, except for younger members of the group, who may receive a larger guaranteed income in their earlier years. Other members of the group could earn equal incomes if practising in small partnerships. To quote from the P.E.P. report, *Medical Group Practice in the U.S.*, citing the American Medical Association's questionary :

> "If the physician's ambition is to make all the money possible in the shortest space of time we certainly would not recommend group practice. If his purpose is to have an adequate income with an assurance of its permanency, and under conditions where he can practise his profession under the most ideal conditions, we would recommend group practice beyond any method we know. In other words, if the physician's motive is to render the best possible service for the greatest number of people for a remuneration which is adequate but not extreme, the plan would be by us highly recommended."

This judgment by American group practitioners is heartily endorsed by all members of this group for the following reasons :

(1) The first advantage is raising the standard and broadening the scope of general practice.

(2) Consultant's opinion and treatment can be made available without delay and with the minimum of expense to the patient. This is of particular importance if an acute abdominal case is involved, or as regards the money factor, in less urgent cases, when the consultant has to be summoned from some miles distant.

(3) If a patient has to go to hospital, he is cared while an inpatient, by his family doctors through his stay, with immense personal advantages, compa with treatment in a hospital remote from his hom where care, though efficient, may be very imperson Patients have less dread of illness if they know th they remain throughout under the care of known an trusted doctors. There is no reason why group medici should lead to an impersonal attitude of doctor to patien

(4) The combination of general practice with specialis tion has a highly beneficial effect on the specialis making him more practical in his approach to th patient's problems, and making him *think in terms* patients and not in terms of diseases. An addition benefit is gained by the specialist in doing more wor in his own line (thus maintaining and improving h technique) than would be possible if he worked *in th* more restricted field of a small partnership.

(5) Additional services *can* be provided by a grou which smaller practices cannot afford. An instance this is the introduction in this area, within the la two years, of two specialists in anæsthesia, a seco surgical specialist, and a physiotherapist, none of who might have been available if the previous arrangement individual two-men partnerships had been retained.

(6) The "staggering" of *consulting-hours* can ma one doctor available at the group consulting-roo throughout almost the entire day. This is convenie for ambulant patients, besides ensuring that one doct is on call for urgent cases.

(7) Not only can locums be dispensed with but wh one doctor is on holiday another doctor who is famili to the patient and conversant with his case can take place.

(8) Minor advantages are the sharing of facilities medical education, given by an efficient *practice librar* and continual discussion of medical problems wi experienced workers, together with the continuo stimulation of enthusiasm which work in a good te provides.

(9) Group practice helps to prevent the staleness a "out-of-dateness" which often afflict the middle-ag general practitioner. This type of practice affords a excellent alternative for the keen well-qualified youn doctor, who previously had to choose between gener practice and pure specialisation.

(10) Service with an efficient group is an excelle training in domiciliary medicine for young graduates.

No disadvantages have been found by workers this team, either to patients or to themselves. Th dangers of "mass-produced" medicine have bee carefully avoided, and any attempt to create a monopol or to restrict in the slightest degree the patient's fr choice of general practitioner inside or outside the grou has been rigidly excluded.

ENDURANCE OF A GROUP

The difficulty in personal relationships within th group has been fully realised, and guarded against as f as possible by careful selection of entrants and by a equitable and comprehensive partnership agreemen Agreeable wives are as important to a practice as co patible doctors, and this too has been borne in min The endurance of a group largely depends on co patibility of temperament of the partners and the loyalt of their wives. Without such compatibility a grou is likely to degenerate into a mere financial partnershi or else to break up. The health of this group depend on the enthusiasm and liberty of action of the partner (within the broad limits of the partnership agreement). If a partner proved unsuitable for the practice (or afte a satisfactory period became so), and if the other partne could not remove him on grounds of *incompatibility* the effect would be very serious.

when I was lifted on to the bed-pan and only grunted and swore.

To disguise our emaciated pallor I and some of my immediate neighbours who were in this swindle asked be carried outside so that we could get sunburnt. At t things seemed to be going well. With the aid of the rd physiotherapist I sat up in bed and tried to bend y right knee on the amputated side over the bed, the her one being in plaster. Here indeed was progress: er the edge of the bed went my amputation, and couraged by the rest of the ward I bent the knee— thought I did, but the knee flexed only a matter of . This was stark tragedy. For 2½ months I had been nning my life on the lines of one ankylosed knee and e below-knee amputation, and now it looked as though re must be two ankylosed knees and an amputation. few days later I had to face the fact that all was not ll with the amputation, in spite of the most careful rgery and untold mega units of penicillin. The atten- n of the ward M.O. was drawn to my discovery by the und of suppressed weeping from behind a screen, for had found the right tibia making an unexpected pearance through the skin. I had developed a seques- um. Once again new plans had to be made and another ce of ill fortune digested.

By this time I felt that about everything in the book d happened to me and that all would be plain sailing. iling was the operative word, for a few days later three us were told that there was room for us in a ship ling next day. This was a real piece of luck. Our ir was out, we were bathed and changed, and the n in the next bed with a fractured spine somehow cked for me. The last of our carefully hoarded whisky s shared out and swallowed, and with the aid of a pnotic we settled down for the night with a great fusion of thoughts. Further confusion was added as e went to sleep by the night sister telling us that the had been cancelled. Next morning gloom lay in dark layers all round the ward. At midday the ter burst in waving a chit and announced that if uld be ready in an hour we could go. The sun through, another bottle of whisky was produced, another phase was over.

We landed at a West of England port and were delivered hospital trains to an E.M.S. hospital, where we were dled like fragile porcelain. Here I had a first sight my wife, and my secret fear that she would be repelled a limbless man was soon dissipated. Self-confidence an to grow as my family came down from the north visit me, and when friends made arduous war-time urneys to spend an hour with me. I did not see that y in their eyes which I had dreaded since I was unded. I was soon moved to a hospital nearer my me where I could be looked after by my favourite rgeon. A few weeks later it was decided to do a questrectomy on my amputation. This went off y well and all appeared to be under control nically.

A further blow was in store. This time it took the form a red-tabbed Army colonel who gave me a medical ard, announced that I was no further use to the Army, aded me category E, asked what my plans were, and ggested the "psychiatry racket." His idea was that should be carried in on a stretcher to learn all about it psychiatry clinics. This was rehabilitation on the and scale, especially as I had estimated that I would another year in hospital. Being graded category E as really bad news for it meant that I must henceforth st on a disability pension. However, with the aid of y friends I was given a respite and my discharge ncelled.

My left knee was still painful, but I no longer needed sit on an air cushion and I could lie down and sit up t will. Another few weeks and a further reamputation was performed to mobilise an adherent scar. It was done by a personal friend and the anæsthetic was given by an old colleague of mine. The result was a secondary hæmorrhage, and I felt sorrier for them than I did for myself when a few days later a rather exsanguinated amputee had to be whipped down to the theatre to be religatured. Soon after this I could lift my ankylosed leg with the plaster on without too much pain. I went out in a spinal carriage to the cinema and to that mecca of all men in bed—a pub. Shortly afterwards I essayed a wheel-chair, and here at last was true independence. With my leg stuck out in front I could propel myself round the hospital; I could attend the physiotherapy department and have active exercises with my right knee, which was now flexing to 50°. After three months the day came when my calliper was delivered, but after being forced upright on to crutches I found that will-power alone was not sufficient to lift myself long. A month of exercises and it was just possible to make progress.

The next milestone was when I got my artificial limb, and, with a calliper on one side and an artificial limb on the other, I walked. This was the day I had dreamed of. It was an erratic, wavering, shaky walk, but I was proud of it. Several weeks later I was offered a job doing medical boards, when I was out of the Army. Accordingly I travelled to London, was boarded out, shaved off my moustache, and danced at one of the more fashionable hotels. This was a huge success, for I was not the complete social outcast I had anticipated. I started doing medical boards and felt that for the first time for 18 months my existence was justified. I was actually doing something to keep my place in society. Then a post was offered me in a Ministry, and after a London interview I was accepted. By good luck and unremitting endeavour I managed to obtain an unfurnished flat in London and have lived there for the past three years. A year ago I was appointed to the permanent pensionable staff of this Ministry and am working alongside fit men and not in any sense a passenger. In fact, ambition keeps biting me to undertake a job where there is more work and movement. I walk without a stick or calliper and have developed my own mode of life for entertainment purposes. At theatres and cinemas I take a left-hand seat and put my ankylosed leg in the aisle on a small folding stool, where it is not so noticeable as might be expected. The reason I rest my artificial leg on a stool will not be far to seek if any six-footer will try sitting down on a chair with his leg straight, for it either means sitting on the edge of a chair or sitting with the spine extended.

In my usual restaurants I am well known and when I sit down an unobtrusive chair is provided on which to rest my leg. I drive a car, dance occasionally, and go swimming when I can obtain solitude and freedom from curious stares, for my method of entering the water is unorthodox as I cannot hop and do not wear a prosthesis. I am a chronic spectator of all kinds of sport and have stood through two rugby matches one after the other on several occasions.

I still feel sure that had the surgeons yielded to my pleas to amputate this limb, life would have been much more comfortable and I still would have walked without sticks. However, there is still the chance of an arthroplasty when the results are a little better. I have patches of depression and frustration three or four times a year, but fortunately both my wife and I recognise them for what they are and take the necessary steps. Altogether life is a great improvement on what I had anticipated four years ago, but nothing will ever convince me that an ankylosed or arthrodesed knee is a good thing to have. Of the things that irritate me, one is being called a cripple as opposed to disabled, and another is having my amputation referred to as a stump.

be abolished, and a new form of claim substituted. This would consist of a single sheet giving the date, the name and address of the patient, the type of service rendered, the total fee charged, and the amount claimed from the fund, with a certificate at the bottom, signed by the doctor, that the claim was a true one. There would be two checks on the genuineness of the claims, (1) a scrutiny of the practitioner's records by a medical inspector, and (2) postal inquiries from a proportion of each practitioner's patients. In thus handing out what is to all intents and purposes the equivalent of a blank cheque the authorities may not be as green as they seem at first sight. There have undoubtedly been abuses of the old system, but it has been almost impossible to bring them home, for under the present system there have to be two parties to a fraud, and one of them, the patient who has signed a misleading receipt, is not likely to appear as a witness against a doctor and thereby admit his complicity.

The committee's report consists only of recommendations; and many, if not most, of them are sure to be the subject of controversy. One thing is certain—that the present system, a pioneer in the field of socialised medicine but one that has never been thoroughly overhauled, is in need of a spring-clean.

ORGANISATION OF CANCER SERVICE

WHEN, in July, the governing body of the Liverpool Cancer Control Organisation transferred their responsibilities to other hands, the Organisation had existed for some ten years; and in the light of those years of experience a series of principles has been formulated, and printed in the annual report,[1] for the guidance of those who will now have charge of the service. These principles were laid down when it became clear that, contrary to the Organisation's hopes, the radiotherapeutic centre was not to be an integral part of the teaching hospital.

The first principle laid down is that the respective duties of the regional hospital board and of the board of governors of the teaching hospital in regard to the diagnosis and treatment of cancer are distinguishable but complementary, and that the utmost coöperation is desirable. The regional board's duties should be to provide diagnostic and therapeutic services in all suitable hospitals, including the teaching hospital, and to afford such facilities for teaching as the university may require. For their part, the board of governors should provide, as part of the regional board's service, arrangements for diagnosis and treatment of patients attending the teaching hospital; and they should ensure that these arrangements are sufficient for undergraduate teaching.

Thus the requirements of the regional hospital board comprise: (*a*) from their own resources, a regional team of radiotherapists, medical staff other than radiotherapists employed in regional hospitals, and a headquarters institute for the radiotherapeutic staff; (*b*) from the teaching hospital, medical staff other than radiotherapists employed in the teaching hospital, such treatment facilities as the teaching hospital can provide, and the ancillary services of a general hospital.

The requirements of the board of governors of the teaching hospital comprise: (*a*) from their own resources, medical staff other than radiotherapists, and treatment facilities for complete undergraduate instruction; (*b*) from the regional board, the services of visiting radiotherapists, and access to the radiotherapeutic headquarters institute for such treatment as cannot be provided in the teaching hospital.

The essential condition for an efficient service, says the report, is joint diagnosis and treatment by radiotherapeutic and other medical staff, except where, by full agreement, treatment is conducted solely by one or the other. A cancer diagnostic service staffed by one or other of these two groups alone is thus preclude and such an arrangement is also ruled out for the reas that: (1) the volume of cancer cases arises from an less than the total volume of initially undiagnosed ca attending hospital; (2) diagnostic services being nee in all suitable hospitals, a single hospital is inadequ for the purpose; and (3) from the patient's standpo the diagnostic services are best located in the nor centres of hospital service and not in a hospital ide fiable as a cancer hospital. Furthermore, hospi beds should be allocated to radiotherapeutic and ot medical staff according to the proportions in wh purely radiotherapeutic and joint treatment are lik to be employed.

The administrative arrangements recommended in report include the establishment of a cancer servi medical advisory committee to assist the regional boa

---

Disabilities

16. LOSS OF A LEG

AT about midnight $4^1/_2$ years ago the blast of a Germ Schu mine took my right leg off. I knew what h happened—it was not necessary to soldier in Italy lo to encounter this situation pretty often in others—a my mental condition was not improved by my thinki that I had been blinded, for I could see nothing and cou not feel my hands. At that moment I felt so unutterab lonely that my instinct of self-preservation fled entirel and a vivid memory is of my head falling to the grou in a helpless despair. Then light dawned, in the lite sense, and I found I could see again. It was only trac shells, but it was vision, and from that moment m efforts at rehabilitation started.

After the usual progress " down the line," with perio of semiconsciousness in which comforting faces ma fleeting appearances through mists of sleep, morphin and pain, I arrived in a general hospital not far fro Naples, and when at last it was possible to take an intere in my environment I found myself in a ward full o amputees. True to form—" doctors and nurses neve have anything straightforward "—everything wen wrong with me, and after a series of operations, reamp tations, plasterings, and splintings, I realised tha must face the future with my right leg off below th knee and my other leg ankylosed at the knee with foot-drop. My arms were still in bandages but the were going to be all right.

I knew that further surgery was pending, so I set mysel targets to attain over the next year, which I estimate would be spent in bed in varying degrees of pain. Th first target was to get back to England to see my wif whom I had left $3^1/_2$ years before; for the thought o seeing her again had borne me up in my worst moment of emotional upset and churlish tantrums. If you ca imagine the worst pain *you* have ever *felt* concentrate into one small part of your body you will know what i means to have a pyarthrosis of the knee. Even slee offers no release, for directly the muscles relax th starting pain in the knee comes back and full conscious ness is regained with a scream.

This was my life for three months—lying in be watching other wounded being carried into the war and seeing them walk out again while I remained stati having three-hourly shots of penicillin, watching bottle dripping blood into me, and listening to the rumble o Vesuvius and the guns from Cassino. In the last of thes months I realised that a very serious effort would hav to be made if I was to get back to England. All the friend I had clung to in the ward were being evacuated, and her I still was. So I embarked on a campaign of saying I felt fine, for by this time my leg was in plaster and the knee becoming less painful. I also forebore to scream

Letters to the Editor

THE FULL-TIME SPECIALIST

Sir.—At the last meeting of the Leeds Regional sultants and Specialists Committee, following a ussion upon domiciliary visiting by full-time cialists, it was decided that no full-time specialists uld be allowed to take part in the scheme for iciliary visits with or without pay; that any such would impinge upon the prerogative of those cialists working part-time in hospitals; and that, as profession was solidly against a salaried service, cialists should be discouraged in every possible way m remaining full-time and should be encouraged these financial penalties to take up part-time k.

n this region most of the consultants I know are loyed the maximum of eight sessions per week in pital. With the weighting already given, and iciliary visiting, they will be receiving, for about hours a week, the remuneration of the full-time ialists, who have no time-limit to the hours worked who are in many cases now doing 40–50 hours a k.

it the opinion of the profession that specialists are be discouraged from working full-time? That they to be prevented from indulging in professional ivities outside their hospital work? That appoint-ts under the boards are to be limited as far as possible part-time specialists, and full-time appointments not going to be made except in very special umstances?

ncidentally, the Leeds regional committee is in my ion an illegally constituted body. Its constitution decided upon at a meeting of a committee represent- the non-teaching voluntary hospitals, who arbitrarily ded to exclude hospital areas from participation e the hospitals were mental, fever, or tuberculosis.

LOCAL INFECTIONS TREATED WITH DIBROMPROPAMIDINE

—Lest the article by Kohn and Cross, in your of Oct. 23, engender false optimism, we feel it ary to record briefly our experience of local chemo- py with dibrompropamidine isethionate ('M. & B.). Using a 1·5% cream in the carbowax base recom- led, we have now treated 8 inpatients (6 burns, dermatitis) suffering from surface infections with domonas *pyocyanea*. The cream was applied for ods of four or more days. In 4 of the cases it was lied daily, and was combined with perfect dressing er which minimised the possibility of added infection. no case was appreciable clinical or bacteriological ovement noted. All the strains of *Ps. pyocyanea* ted were inhibited in vitro by 1:1000 dibrom- pamidine.

On the other hand, our results confirm the effective- of dibrompropamidine in treating surface infections to *Streptococcus pyogenes* and *Staphylococcus aureus* uding penicillin-resistant organisms). The bacterio- al findings have been clear-cut, and the clinical lts good. We would recommend the use of the drug re penicillin-resistant organisms are found, and in ients previously sensitised to penicillin. Controlled ls are now commencing, and it is possible that for e organisms a less concentrated preparation will ce and be less likely to have undesirable side-effects g., toxicity to leucocytes). It is also hoped to estigate the use of the drug as a prophylactic against *pyocyanea* infection of burns, for it is not impossible t a drug might pass this test in spite of its failure as a rapeutic agent.

TREATMENT OF BURNS

SIR,—With fashion rooting about in the past for something to whet our jaded appetites, may I make a plea for the *resurrection of tannic-acid jelly?* I have used this agent for many years and still believe it to be the best of all protectives for severe burns.

The excellent article by Dr. Colebrook and Dr. Hood (Oct. 30) suggests to me that results, when it is properly used, are consistently good because a thin film of it approximates to the ideal flexible membrane postulated as a necessary guard against "infection through soaked dressings."

Dr. Gissane, as I found on a visit to the Birmingham Accident Hospital during the war, certainly picked a winner in 'Cetavlon' as an initial cleansing agent. After using this I apply a thin coat of tannic-acid jelly and a single layer of gauze. This is allowed to dry as far as possible before packing with cotton-wool. On subsequent days more jelly is added to repair sodden areas until a firm dry scab of gauze and jelly covers the burnt area. Healing is usually rapid, and the artificial scab flakes off or can be removed like autumn leaves.

Naturally, with advance of knowledge we have added sulphonamide and penicillin to the local and general treatment. This diminishes unpleasantness, as the method has something in common with the Winnett Orr plaster for osteomyelitis and external appearances are far from elegant. My last case was a large second and third degree burn of the buttocks and anus in a child of 3. It required some fortitude to persevere with the outwardly dismal dressing. But the boy was discharged healed without a scar.

There is one considerable word of warning: *never encircle a limb or finger with a gauze dressing.* If the burns involve the fingers, make a series of half-hoops back and front till the swelling subsides. With this precaution one can even treat third-degree burns in babies. A recent case of palmar burns down to the flexor tendons in a child of 2 who grasped the element of an electric fire gave us complete healing and function in two months.

Lastly, since using this method I have not had to resort to skin grafting. But there is no reason why in a sufficiently extensive raw area both methods should not be combined. I do not think the skin graft would mind.

Walmer. JAMES S. HALL.

APPLICATION FOR HOSPITAL POST

SIR,—It is in the backwash of an emotion compounded of anger and confusion that I address this letter of inquiry to you. What is the policy adopted in the selection of candidates for interview and eventually for appointment to a post advertised in this journal?

I applied two weeks ago for such a post at a well-known hospital near one of our university towns. I received no acknowledgment of my application, and it was only from a chance remark of a friend that I learned that the interview was today. Having made an exhaustive search to find a mislaid letter, I went to the trouble and expense of telephoning the hospital. Believe it or not, the secretary was angry with *me* for inquiring about my application, and quite furious when I asked him how candidates were selected for interview, telling me that it was none of my business and a hospital affair. May I register my protest here? It is my business, and should be a public affair. He finally apologised for not sending a letter of acknowledgment. This was due to an oversight, though it leaves me in some doubt whether my application ever received any attention. It would seem that more tact and consideration are applied in obtaining the services of a cook than those of a doctor.

To most of your readers, this issue is one which they have forgotten, though at some time most of them must have had some similar experience. Heaven knows how much preselection and wire-pulling contribute to an eventual appointment; it was ever so, and I suppose always will be. But is it not farcical widely to advertise a post when the record of appointments to a hospital shows that those chosen are almost always students from the nearby university town?

In England Now

A Running Commentary by Peripatetic Correspondents

AFTER his talk to the Eugenics Society last week[1] Mr. Cecil Binney should have spent the next evening at the Torch Theatre and blushed for his shortcomings. In Mr. Dan Sutherland's *Breach of Marriage* he would have seen an eminent lawyer who—without any trial run, with no chance to consult a single text or ring up a knowing colleague, and moreover with none of that tiresome legal caution which Mr. Binney displayed —was able to rattle off all the relevant opinions on artificial insemination at a moment's notice; and this, too, when he was rattled himself, having just been told that his coming grandchild was to be what some have called a test-tube baby.

On the whole he took it well; though one of the curious things about this play is that no-one can be sure how anyone is going to take anything. Certainly they have a good deal to take. There is Peter Stuart, the war hero, for example, paralysed "from the waist down" as result of frostbite. This obscure condition does not debar him from having a child, though it requires the intervention of a third party. He is alleged to be going crazy in his desire to achieve this feat; but all the poor fellow betrayed was a very moderate snarkiness with his wife and in-laws—a touch of veteran's rage, perhaps invited by their aggressive forbearance. Well, but then he turns out to have pulmonary tuberculosis, diagnosed in the course of the afternoon by the clever doctor, Erasmus Baring, who happens to know a bit about tuberculosis, he tells us; and so he must, for he spots a minimal lesion without an X ray, and mainly on the basis of a positive Mantoux test. He is weak on modern treatment, though, and shockingly hazy about the dangers of infection for the child. Never mind, the play must go on, rather better than expected. Peter must not be told about his tuberculosis, which (if he were to be the donor himself) might be passed on to the next generation; but at all costs he must be given a child; so the wife plumps for A.I.D. and Peter must never know about that either. But of course he finds out, and like the audience at once engages in the pastime of spotting the donor; as there is only one candidate it doesn't take anybody long. So the war hero, after a last well-ridden row with his wife, wheels himself over the cliff, as we all knew he would the moment we heard there were cliffs in the vicinity.

What, I wonder, was Mr. Sutherland out to say? He gives the doctor every sympathetic consideration and most of the best lines, which suggests a liberal attitude to artificial insemination. On the other hand, the whole affair turned out very badly, and ought to be a lesson to somebody. It is hard to detect exactly whom. But there, as Mr. Binney might say, perhaps it will never happen.

* * *

My peripatetic colleague of Oct. 16 who suffers so severely over his winter pants might obtain the appropriate regulation of clothing without so much heart-searching by the use of an overcoat, and there is a tradition in the Eastern Counties that overcoats should be looked out at the time of Barnet fair. This fair, which is now a ghost of its former self both in size and importance, is held on Sept. 3, 4, and 5, except when one of these days is a Sunday.

* * *

Should a doctor tell? And, if so, how much? The old question came up again the other day. Miss O, a woman of 55, has been under the care of our partnership for 6 years with spasticity due to disseminated sclerosis. We have told her that her trouble is "neuritis" (convenient blanket-word!) and encouraged her to continue at work, and she does quite well with a little morning amphetamine to get her going.

A few weeks ago she was staying in a provincial town and fell sick. On her return she told me that the doctor, a young and enthusiastic physician, examined her thoroughly and warned her that she had a serious disease which would develop over a long period and ultimately paralyse her; it was called Parkinson's disease. I deduced that the doctor had probab diagnosed her correctly but was not quite at home wi the nomenclature. Anyway, it gave me a loophole, a I assured her that she had not Parkinson's disease, a that, though we might give her trouble a long latin nam "neuritis" would do quite well, and that she need n worry for the future.

Twenty years ago I might have been less subt. And then when she heard the name "disseminat sclerosis" she would have looked it up in the *Compl Home Doctor* and become a very unhappy and perha needlessly apprehensive woman. I once saw a wom in the fifties who had recently developed a typ spasticity and incoördination having had no sympto whatever since her original attack of diplopia at t age of 20. That helped to teach me not to darken t lives of my patients with dire prophecies.

It is more difficult to know when to tell in cases approaching death. I think I should like to know if had an inoperable cancer or an acute leukæmia, b I don't think this would be true of most people. O gets the "feel" of patients, whether they want the tru or not. Usually it is best to await their approach, a often the form of question helps to determine the answ One of my best patients and friends—an intellige inquisitive, and humorous old man—asked me single question about his trouble during a long illn with an inoperable bowel cancer. Sometimes the ne relatives can help, but usually it has to lie betwe doctor and patient. A dear old lady of 80 said "T me, doctor, I'm not afraid"; and so I told her, and the many months she lingered on she always had a sm and usually a joke. But for many others the truth wo have been mental torture.

And with Pilate one may ask, "What is truth At the best we can only tell some of it, for we never kn the whole.

* * *

Minor swindles on the Government are the fash these days, but here is one which I am assured is be perpetrated and must be among the simplest and saf All you require is a friendly chemist and a busy doct The technique is as follows: Go to the doctor's even surgery; you will probably be one of 100-odd patie there. Complain of a "cough" or a "lump in t throat," or anything which takes your fancy and does sound too alarming. The doctor may or may not exam you but at any rate he will give you a prescri Take the prescription to your friend the chemist and [illegible] it with him for some toothpaste, hair oil, or cosm for your lady friend. If you want some more, simply on attending the busy evening surgeries. Always say th the last prescription did you good, and you will certai have it repeated. There's no end to it.

* * *

Your provincial and peripatetic psychiatrist h recently been asking his colleagues in London and New York: "How do you practise psychiatry in t great wen, this monster, called the Metropolis, anywa When I see a patient in my home town, I can visuali the street he lives in, the school he went to, the facto he works in. I probably know his family doctor—or h probation officer—personally. A good rapport m exist because I have already treated his cousin or h next-door neighbour. After he goes back to work can attend as an outpatient shortly after 5 o'clo without any inconvenience to anyone. There's soci psychiatry for you." The metropolitan psychiatris have their answers. They point to their retinues social workers and their piles of reports from soci service agencies. They too have faithful patients wh travel 20 miles to the hospital if they move out to t suburbs. They too can visualise their city district even the non-peripatetic reader may understand t connotations of "Lower East Side" and "Harlem and of "Fifth Avenue" and "Park Avenue."

* * *

We are becoming inured to jargon these days, bu I was somewhat startled when my youthful secretar asked me to sign a letter I had dictated to a docto about a woman patient, recommending ". . . extr rest, absenteeism from intercourse, and careful regulati of the bowels. . . ."

DENTURES AND ANÆSTHESIA

SIR,—Are there not two simple ways of obtaining tight fit for edentulous patients, which do not require cial apparatus or expose dentures to risk of fracture? swab of normal theatre size packed into each cheek und the airway or tube (unless the nasal air passage assured) will bring the face to a good round contour. which a face mask fits well. A really large face-piece the old conical, unmoulded type will "sit" so far out the face that the edentulous collapse is usually ed, and a good fit is far more likely than with any the patterns of small mask. Unfortunately these large ks are now difficult to buy. The principle of fitting bony margin of the face is the same as Mr. Phillips plying with his inhaler.

E.11. J. BARNARD.

CRISIS ON QUALIFICATION

SIR,—The annotation entitled The Prentice Practice in your issue of Oct. 23 has aroused considerable rest among some who hope shortly to be the object the arrangements proposed by the Minister of Health. writers of this letter are students of a London ital who have had their medical studies interrupted six or more years of war service and feel considerable cern over that part of their training which will begin n as they qualify.

In the next twelve months a considerable number of Service students will be finishing their undergraduate es at the various medical schools and colleges: the following year this class of students will amount ut half the total qualifying. Still another year e proportion will be even higher. The average ex-Service students on qualification is, or will be, 30. It is realised that in a few years, although ll ex-Service element may remain because of iption, the age will be considerably less. Owing ir age, this present group (a result of the recent has certain problems which deserve consideration such schemes as the present one are worked out. y of these students are married and have children; although the Ministry of Education is paying tenance grants to most of them, nearly all of them suffering real financial hardship, as their gratuities savings are soon exhausted. On qualification these ts cease abruptly, so that, unless some measures instigated in the immediate future, very few will able to apply for house-appointments, which are a essary part of medical training. The present rate of for house-appointments will almost entirely preclude who have a family to feed, clothe, and educate n applying for such appointments. By the simple ideration of averages, the ex-Service group must ain a number of men of ability. Many, too, were ed for, and held positions of, considerable responsiy in various arms of the Services. Surely any such , training, and experience will have its uses in the ssion. It will be regrettable if a certain number men from sheer necessity short-circuit some aspects their training and offer their services to the highest der.

We feel most strongly that the salary for house-ntments should be uniform throughout the country that there should be a definite scale, taking into sideration such factors as age, and number of pendants. The Minister of Education has adopted a ale for students' maintenance on these lines, and the vices, too, pay their personnel in a similar manner.

After house-appointments, those of us entering general ractice will welcome the latest suggestion for further aining under experienced general practitioners. With regard to the salary mentioned by you and to which the Insurance Acts Committee has objected, we feel that this is not, in all conscience, too liberal. The principal will have, as you point out, fully qualified, enthusiastic assistance and all that this means to someone who must be feeling the effects of a life of unstinted labour. From the assistant's point of view, he will almost certainly have to take temporary furnished accommodation for his family, which alone will cost him at least five guineas a week. (We know, we have had to pay it.)

These are hard facts and not flights of fancy which we have put in this letter. We appreciate that it is easy to criticise and difficult to construct, but we hope that by raising these problems we may enable the highest standards in medicine to be maintained by ensuring that the newest members of the profession may follow the excellent paths which have been, and are being, laid down for them.

RETURN TO PHILANTHROPY

SIR,—In last week's leading article, is the sharp antithesis between "the enthusiastic gatherings of the hospital contributory schemes of a decade ago" and the meetings of a regional board quite justified by the structure of the new organisation? The contact with the people is through the management committees rather than the regional board.

Camberwell provides an example. Ten days ago the mayor presided over a large and representative gathering of voluntary workers in, and friends of, the three hospitals (formerly L.C.C.) of Dulwich, St. Francis, and St. Giles. Mr. Lesser, chairman of the Hospital Saving Association, accompanied by many of the local group secretaries, spoke in advocacy of the formation of the Camberwell Hospitals Fellowship, which was constituted by those present. The fellowship will be formed by various groups and friends of the hospitals. Patients will be the first group, under the guidance of the Vicar of Camberwell, who has been a patient. Librarians, who are already doing excellent work for the patients and other voluntary workers in various capacities, will elect their representatives to form, with representatives of the patients, the governing council of the fellowship. Thus there will be a representative organisation to which the management committee can render an account of their stewardship annually. As patients will have a preponderant voice it will represent the "consumer interest" which can only be found with much difficulty in other public-service undertakings.

C. E. A. BEDWELL
Chairman,
Camberwell Hospitals Management Committee.
Dulwich Hospital, London, S.E.22.

Public Health

Mobile Dental and Medical Units

PROMPTED by the unsuitability of some of the existing temporary dental clinics, Kent County Council's primary-education and welfare subcommittee has recommended that a mobile clinic should be provided for the school health service in country districts. The units, of which there are likely to be three, will be drawn in turn by a single "mechanical horse." The trailer portion will contain a waiting-room, surgery, and recovery room, and will have its own X-ray apparatus and electrical system. Where a mains supply is unobtainable, water will be drawn from built-in tanks.

The *Empire News* (Oct. 24) reports that a travelling surgery will soon be operating in the rural district of New Earswick, Yorkshire. A caravan, drawn by a shooting-brake, will be partitioned into a reception room, a consulting-room, and two small dressing-rooms. The surgery is being sent out by the Rowntree Village Trust with the backing of the Ministry of Health; and if it is successful further units of the same sort may be introduced.

Furthermore, what is meant by the phrase "Required—house-physician, A or B2"? Does it mean that this is a first appointment open to newly qualified practitioners, unless an ex-Serviceman or registrar with an M.R.C.P. cares to apply? Or, more charitably, does it mean that a post normally of B2 status is found difficult to fill and offered to A practitioners?

To many, I said, this issue is dead. To me, and to many other newly qualified men, it is very much alive.

A. B.

BLOOD FOR TRANSFUSION

SIR,—In view of the recent correspondence and last week's leading article on this subject, I think it is worth recording that recently we obtained 30 pints of group-O blood from the North London Blood Transfusion Depot for the purpose of exsanguination transfusion. We are particularly indebted to the director of this unit for his help in supplying this large quantity at short notice.

St. Bartholomew's Hospital, London, E.C.1.
I. P. MACDOUGALL
Chief Assistant.

NITROUS OXIDE SUPPLIED BY PRACTITIONERS IN MIDWIFERY SERVICE

SIR,—There appears to be confusion about the supply to general practitioners of cylinders of nitrous-oxide gas for analgesic purposes in maternity cases under the National Health Service. As the National Birthday Trust is particularly interested in the provision of analgesia to women confined in their own homes, approach was made to the Ministry of Health for guidance in the matter; and the following is from the Ministry's reply:

"The position is that if a doctor is engaged by the patient to give maternity medical service under part IV of the Act, he is in the same position as any doctor giving general medical service under part IV. He may write prescriptions or may himself supply any drug 'personally administered'—e.g., nitrous oxide. For drugs so supplied he will receive payment from the executive council on presentation of a claim on E.C.10 to the executive council.

"If the doctor is called in by a midwife in emergency, he is not giving maternity medical service under part IV of the National Health Service Act but is giving services under the Midwives Act, 1918. He receives a fee which includes the supply of necessary drugs and dressings, except that he gets extra payment for certain expensive drugs named in part 2 of the schedule to S.I. 1463 of 1948. In such cases, the patient would have a midwife in attendance and, as you know, midwives are supplied by the local health authority with cylinders of nitrous oxide. Many, but not all, doctors have cylinders but some may not have realised that when giving maternity service under part IV they can be paid for any nitrous oxide they supply themselves."

D. V. RIDDICK
57, Lower Belgrave Street, London, S.W.1.
Secretary, National Birthday Trust Fund.

MEDICAL RESEARCH IN AFRICA

SIR,—I am very glad that your correspondent of Oct. 16 (p. 624) has called attention to the attitude (or lack of it) of the Colonial Office to the immense medical problems of Africa. I note that he makes no reference to venereal diseases, but in this respect the official attitude seems to be much the same as in others.

During 1944 and 1945, as Command venereologist and dermatologist to the British Army in East Africa, I devoted fifteen months to the study of the special problems of venereal diseases in these territories. The war saw an enormous increase in the incidence of venereal diseases in East Africa, and at the same time provided means by which that increase was likely to go on. In this respect the V.D. problem has an urgency not presented by such a condition as malnutrition, which was presumably not changed very much in recent years. It is also comparatively remediable; yaws has been virtually "stamped out" in many districts, and comparable medical "campaigns" on a larger scale would do much to control the spread of venereal diseases.

Three times since the end of the war have I tried to induce the Colonial Office to show an interest in the problem. I have submitted a survey of some 3000 words, called twice at the Colonial Office, and written letters; but I have never detected any spark of real interest. My correspondents in Kenya are still unable to
tell me of any material steps which have been ta
cope with the situation in that country.

No doubt, as your correspondent says, ther
shortage of personnel to do the work; but I a
satisfied that this is the reason why so little ha
done. The official mind does not seem to be ap
at so many tasks and so few people to carry ther
its attitude more resembles indifference, which ca
result from a lack of appreciation of the importa
the work or from apathy. So long, of course, as
the attitude of Whitehall the field workers of the C
Medical Service will be frustrated in their work
if they are good doctors, many of them will lea
service as soon as they can.

Meanwhile, what of our trusteeship of the Afr

UNDER TENSION

SIR,—In his letter on Oct. 23, Dr. West insi
that because I admit the obvious fact that the Mu
rulers wish to destroy non-Communist States, I
therefore be a warmonger intent on a preventi
against the U.S.S.R. This is a very serious c
which I deny. In everyday life, a man who is thre
by a homicidal paranoiac neither reflects, while av
the mortal stroke, that it takes all sorts to make a
nor decides to murder him first. He does the com
sense thing. If he lives in an ordered and p
State, he calls on the police to protect him, a
no doubt hopes that psychiatrists will cure the par
of his mental aberration in due course. If, c
other hand, he lives in a State without police
courts, or psychiatrists, he collects trusted friend
fortifies his house.

This is my logical counter to Muscovite threa
am fortunately able to answer Dr. West's whi
question about what voices are to be heard in the U.
In the Stalin-Tito exchanges, Stalin writes that th
that there can be "peaceful development of cap
elements alongside Socialism is a rotten and oppor
theory." Stalin also said, in the same Tito-Comi
controversy: "Communist parties can live and de
only in open warfare against the enemies of
munism." Dr. West's counter to these bloodt
threats seems to be that no-one is really to blam
that it will all be the same in 40 years. Very whi
very. A mighty droll and fantastical fellow, 'po
word.

STAPHYLOCOCCAL ENTERITIS DURING STREPTOMYCIN THERAPY

SIR,—At the end of the case-report admi
presented by Mr. Kramer on Oct. 23, I was surpris
find in the summary the suggestion that "the
aureus, already present elsewhere in the body,
rendered streptomycin-resistant by the small amou
the drug absorbed from the gut."

In the absence of proven facts the subject is on
speculation; but it is of great clinical import
My experience is limited to penicillin, about
similar suggestions are frequently made. I find
larly after giving normal dosage of penicillin for 2
days in proper cases and failing to obtain improve
that a characteristic defervescence by crisis is obt
by doubling or quadrupling the dose. I would su
that clinical experience in this and other ways is ag
the theory of education of a bacterial strain to imm
to penicillin.

By an interesting coincidence, in the same numb
THE LANCET Dr. Barber and Dr. Rozwadow
Dowzenko find "that it has not so far been possib
train a staphylococcus in vitro to destroy penicil
Furthermore, in Mr. Kramer's case, the staphyloc
causing conjunctivitis was present on the face and
therefore being ingested before penicillin or streptom
was administered. Why then did it not cause the
enteritis at that stage? Is it suggested that small
of streptomycin not only produced insensitivity to
drug but enhanced the virulence?

I believe Mr. Kramer's second suggestion to be near
truth—"that elimination of the normal intestinal
may have contributed to the establishment of the staph

ccus there." Such elimination was in fact proved. is accepted that the normal intestinal flora is essential o health; and this flora is profoundly disturbed under influence of chemotherapy and antibiotics. Intestinal turbances, sometimes serious in children, often seem occur during the period of relative sterility of the canal. earch on this problem might well lead to interesting clinically useful conclusions.

CRISIS ON QUALIFICATION

SIR,—The annotation entitled The Prentice Practiner in your issue of Oct. 23 has aroused considerable erest among some who hope shortly to be the object the arrangements proposed by the Minister of Health. e writers of this letter are students of a London pital who have had their medical studies interrupted six or more years of war service and feel considerable cern over that part of their training which will begin soon as they qualify.

In the next twelve months a considerable number of -Service students will be finishing their undergraduate es at the various medical schools and colleges; the following year this class of students will amount out half the total qualifying. Still another year he proportion will be even higher. The average ex-Service students on qualification is, or will be, 30. It is realised that in a few years, although all ex-Service element may remain because of cription, the age will be considerably less. Owing heir age, this present group (a result of the recent) has certain problems which deserve consideration n such schemes as the present one are worked out.

any of these students are married and have children; , although the Ministry of Education is paying intenance grants to most of them, nearly all of them suffering real financial hardship, as their gratuities savings are soon exhausted. On qualification these nts cease abruptly, so that, unless some measures instigated in the immediate future, very few will able to apply for house-appointments, which are a cessary part of medical training. The present rate of r for house-appointments will almost entirely preclude e who have a family to feed, clothe, and educate n applying for such appointments. By the simple sideration of averages, the ex-Service group must tain a number of men of ability. Many, too, were ned for, and held positions of, considerable responsility in various arms of the Services. Surely any such ility, training, and experience will have its uses in the ofession. It will be regrettable if a certain number men from sheer necessity short-circuit some aspects their training and offer their services to the highest lder.

We feel most strongly that the salary for houseppointments should be uniform throughout the country d that there should be a definite scale, taking into nsideration such factors as age, and number of pendants. The Minister of Education has adopted a ale for students' maintenance on these lines, and the ervices, too, pay their personnel in a similar manner.

After house-appointments, those of us entering general actice will welcome the latest suggestion for further ining under experienced general practitioners. With regard to the salary mentioned by you and to which the Insurance Acts Committee has objected, we feel that this is not, in all conscience, too liberal. The principal will have, as you point out, fully qualified, enthusiastic assistance and all that this means to someone who must be feeling the effects of a life of unstinted labour. From the assistant's point of view, he will almost certainly have to take temporary furnished accommodation for his family, which alone will cost him at least five guineas a week. (We know, we have had to pay it.)

These are hard facts and not flights of fancy which we have put in this letter. We appreciate that it is easy to criticise and difficult to construct, but we hope that by raising these problems we may enable the highest standards in medicine to be maintained by ensuring that the newest members of the profession may follow the excellent paths which have been, and are being, laid down for them.

J. M. BROWN
W. A. BULLEN
G. DOUGAN
I. F. G. MCLANNAHAN
J. F. TRUNCHION.

RETURN TO PHILANTHROPY

SIR,—In last week's leading article, is the sharp antithesis between "the enthusiastic gatherings of the hospital contributory schemes of a decade ago" and the meetings of a regional board quite justified by the structure of the new organisation? The contact with the people is through the management committees rather than the regional board.

Camberwell provides an example. Ten days ago the mayor presided over a large and representative gathering of voluntary workers in, and friends of, the three hospitals (formerly L.C.C.) of Dulwich, St. Francis, and St. Giles. Mr. Lesser, chairman of the Hospital Saving Association, accompanied by many of the local group secretaries, spoke in advocacy of the formation of the Camberwell Hospitals Fellowship, which was constituted by those present. The fellowship will be formed by various groups and friends of the hospitals. Patients will be the first group, under the guidance of the Vicar of Camberwell, who has been a patient. Librarians, who are already doing excellent work for the patients and other voluntary workers in various capacities, will elect their representatives to form, with representatives of the patients, the governing council of the fellowship. Thus there will be a representative organisation to which the management committee can render an account of their stewardship annually. As patients will have a preponderant voice it will represent the "consumer interest" which can only be found with much difficulty in other public-service undertakings.

C. E. A. BEDWELL
Chairman,
Camberwell Hospitals Management Committee.
Dulwich Hospital, London, S.E.22.

Public Health

Mobile Dental and Medical Units

PROMPTED by the unsuitability of some of the existing temporary dental clinics, Kent County Council's primary-education and welfare subcommittee has recommended that a mobile clinic should be provided for the school health service in country districts. The units, of which there are likely to be three, will be drawn in turn by a single "mechanical horse." The trailer portion will contain a waiting-room, surgery, and recovery room, and will have its own X-ray apparatus and electrical system. Where a mains supply is unobtainable, water will be drawn from built-in tanks.

The *Empire News* (Oct. 24) reports that a travelling surgery will soon be operating in the rural district of New Earswick, Yorkshire. A caravan, drawn by a shooting-brake, will be partitioned into a reception room, a consulting-room, and two small dressing-rooms. The surgery is being sent out by the Rowntree Village Trust with the backing of the Ministry of Health; and if it is successful further units of the same sort may be introduced.

Obituary

CHARLES MORLEY WENYON

C.M.G., C.B.E., M.B., B.SC. LOND., F.R.S.

Dr. C. M. Wenyon, who died in London on Oct. 24, was one of the greatest authorities on medical protozoology. He was born at Liverpool on March 24, 1878, but spent most of his childhood in China, where his father, Charles Wenyon, was a pioneer medical missionary. At the age of 14 he was sent back to England to be educated at Kingswood School, Bath. Later he went to Leeds University, and then to London where he studied at University College and Guy's Hospital, graduating as B.SC., with protozoology as a special subject, in 1901, and M.B. in 1904.

In 1905 he was appointed to the first post of lecturer in protozoology at the London School of Tropical Medicine, where he worked under Patrick Manson. In the years that followed he continued his studies in protozoology at Munich and in Paris, and collaborated with the late Sir Andrew Balfour at the Wellcome Tropical Laboratories in Khartoum. He also undertook a number of scientific expeditions to Africa and the Near East: working in a floating laboratory on the Nile, he investigated protozoal diseases in the Sudan, and later he studied leishmaniasis in Bagdad, Aleppo, and Malta. On his return to England in 1914, he was appointed director of research in the tropics to the Wellcome Bureau of Scientific Research. During the war of 1914–18 he conducted classes in protozoology for Army medical officers, and as a member of the Medical Advisory Committee in the Near East visited Egypt, India, and Mesopotamia, where he worked on amœbic dysentery and other protozoal infections. He was subsequently appointed consultant in malaria with the British Salonika Force, and after the war became consulting pathologist to the Army of the Black Sea. He came back to England in 1920, and in 1924 succeeded Sir Andrew Balfour as director-in-chief of the Wellcome Bureau of Scientific Research, later becoming director of research in the Wellcome Foundation—a post which he held until 1944. On retiring from the directorate he maintained his connexion with the foundation as consultant in tropical medicine.

Wenyon's scientific activities, lasting half a century, were not restricted to the purely medical sphere. In fact his name has left an imprint on our knowledge of every group of parasitic protozoa in man and the lower animals. Before the first world war medical protozoology hardly existed, but at the beginning of the second war the relative medical importance of the different human protozoal parasites was fully established. This achievement was due largely to the pioneer work of Wenyon. In Egypt he examined the incidence of amœbiasis and other intestinal protozoal infections, with special reference to carriers of *Entamœba histolytica* and the epidemiology of amœbiasis. Much of our understanding of the intestinal flagellates and their relation to man is due to his investigations. Of the five species now known to parasitise man, two (embadomonas and chilomastix) were discovered by him. These investigations were brought together by Wenyon and O'Connor in a book on *Human Intestinal Protozoa in the Near East* (1917). Wenyon was the first to describe the exogenous development of the human coccidium, which he named *Isospora belli*, and his subsequent researches on the coccidia of dogs and cats brought order out of our confused knowledge of these parasites. He was the first to establish the coprozoic nature of certain amœbæ and flagellates found in human stools and often mistaken for genuine human parasites. He made important contributions to our knowledge of the leishmanias and trypanosomes and the diseases caused by them. He revised the classificat of the Trypanosomidæ and described their cytolo while his work in the Mediterranean area served elucidate the epidemiology, course of infection, diagnosis of the leishmaniases; he was the first to leptomonad flagellates in the sandfly. While work in Macedonia, he made valuable investigations on mala dealing with its epidemiology, transmission, and tr ment, and with mosquito suppression. His experime studies on the development of malaria parasites mosquitoes at low temperatures served to elucid the behaviour of the parasite in the hibernating ve and to account for the occurrence of outbreaks of mal in the spring.

The most important single work published by Wen is his *Protozoology*—a treatise of two volumes, profu illustrated, which appeared in 1926. This work gi the most complete account of all parasitic proto of medical, veterinary, and general parasitolog importance. Unlike most textbooks, it synthes knowledge of the subject and reflects the auth erudition and vast practical experience.

Not the least of Wenyon's achievements was development of the Wellcome Bureau of Scient Research (now the Wellcome Lab tories of Tropical Medicine) fr a modest information centre t scientific institute with an in national reputation, in which fun mental research in parasitology tropical medicine is carried out.

As editor of the *Kala-Azar Bull* and subsequently sectional ed of the *Tropical Diseases Bull* during the last 36 years Wen contributed authoritative criti reviews of world literature on lei maniasis and other protozoal disea He was hon. secretary of the Ro Society of Tropical Medicine a Hygiene from 1920 till his electi as president in 1945. For a quar of a century he was the guiding sp of the society, which has risen to present position largely through energy and perseverance. He w also instrumental in making t society's *Transactions* an importa medical journal of internatio standing. As a person, he w ever ready to help others with his advice, whi was sought by workers all over the world. He w essentially modest and tolerant, and to colleagues und him he was *primus inter pares*.

Wenyon's work was recognised by many awards a honours. For his services in the first world war he was appoint C.M.G. and C.B.E.; in 1927 he was elected a fellow of t Royal Society; in 1933 he became officier de la Légi d'Honneur; in 1945 he was elected hon. life member of t New York Academy of Sciences; in 1946 he was awarded t Theobald Smith gold medal of the American Academy Tropical Medicine; and last year he was elected hon. fell of the Royal Society of Medicine and was awarded the Mans medal of the Royal Society of Tropical Medicine and Hygie

C.A.H.

To his colleagues Wenyon was more than a prot zoologist; he was a great leader in the affairs of men, a there are many who relied upon his sane pronouncemen and his wisdom. It was a sad day when, some 34 yea ago, he decided to leave the London School of Tropic Medicine with which he had been connected for t 10 previous years. In that comparatively short time h had established his department on a firm basis and ha contributed very substantially to the fame and prestig of this school. In my judgment his most solid contr bution was to the Royal Society of Tropical Medicine he founded Manson House as the home of what he forge as a great society. Wenyon will always be remember as its architect. His management of the society' *Transactions* made of them a journal of the highes order.

No-one could have preserved a more friendly outlook his colleagues and to those around him, however ble. He refused to be led into intrigues or entangled quarrels. He was a very brave man. The qualities courage and endurance he showed on many occasions ing the first world war, and in a high measure during long and painful years which preceded his death.

P. M.-B.

The obscurities of protozoal life-cycles produced a siderable literature of controversy and some false rts. Dr. Wenyon was indefatigable in his endeavours keep the main path open, and he entered the polemic na with a conscientious gusto reminiscent of his sionary origin. If one told him that these confusions uld settle themselves in the course of time he would tly maintain that error was dangerous and should be allowed to go uncorrected. He had an obstinate e that things should not be let go by default. There something realistic and practical in his approach the scientific problems that occupied him and his temporaries, and he did not take much interest in t he considered to be theoretical hair-splitting and e or doctrinaire speculation. Indeed sometimes he ed to inhibit his own advance by this sceptical turn his mind. He was a generous and encouraging fellow-ker, and had a robust and unspectacular friendliness t endeared him to those who knew him well.

M. R.

Wenyon had a great personality. He was entirely ffected and utterly honest, without a trace of cant or llectual snobbery. Even the chance encounter with never failed to warm and illuminate the day; ybe he would be jauntily swinging along the street, en with an old walking-stick; maybe he would be his laboratory or at some meeting or social function: always he could make time for a few moments' t to relate some experience or to make some shrewd ment that sent one on one's way refreshed, stimu-ed, and informed. Always was he willing to discuss blems, to examine specimens or material, and help who sought his never-failing aid; but much of his was not fully realised even by those who benefited from it. For example, he gave untold hours to correcting, and polishing manuscripts submitted experienced and meticulous authors to the *ctions* of the Royal Society of Tropical Medicine Hygiene, and other journals with which he was emed; and many writers and countless readers owe than they know to his advice and labour.

have never heard a single person make an unkind ment concerning him—a measure of affection and timony to real greatness. F. M.

ALBERT EDWIN HAYWARD PINCH

M.D. BRIST., F.R.C.S., M.R.C.P., D.M.R.E.

Mr. Hayward Pinch, who died at Bideford on Oct. 14 the age of 81, was the first medical superintendent of Radium Institute, London, a post which he held for years.

He received his medical education at Bristol and St. tholomew's Hospital, taking the Conjoint qualifica-in 1894. At Bristol he had been first entrance lar and he also held the Suple and Clarke scholarships, he later became an assistant lecturer in physiology Bristol University College. At the Army Medical ege, to which he went after receiving a commission the Indian Medical Service, he continued to carry off rds and received in turn the Fayrer, De Chaumont, Montefiore prizes, and the Herbert scholarship. 1896 he took his F.R.C.S., and he served for a period a surgeon specialist in Bengal. After returning to s country he held the posts of superintendent and turer in pathology at the London Medical Graduate ege and Polyclinic and pathologist to the Alexandra spital for Children with Hip Disease. But he became re and more interested in the new specialty of radio-rapy, and Sir Frederick Treves, who was the first sident of the Radium Institute, persuaded him to cept the appointment of medical superintendent there 1909. Thus he became the first whole-time research nician in the specialty. His annual reports of the work of the institute were more than records of successful achievement: they were also guides in brief to contemporary advances in the treatment of disease with radioactive matter. Cautious in his assessment of results and alive to the dangers of the new technique, he characteristically ended an address to the Medical Society of London with Talleyrand's words: *Pas trop de zèle.* His *Clinical Index of Radium Therapy* appeared in 1925 and *Superficial Radium Therapy* two years later. He was also the author of a *Manual of Technique in Radium Therapy.*

When the work of the institute was reorganised in 1930 on its affiliation with the Mount Vernon Hospital, Mr. Pinch, whose health was poor, felt unable to undertake the additional burden. The committee appointed him consulting surgeon to the institute in appreciation of his services during his long tenure of office. He spent his retirement happily in his native West Country, and a colleague writes: "He was full of abounding vitality, and despite exalted Harley Street prognosis. the invalid survived for 18 years. Kind and generous, he was a sound clinician, especially good on eyes. Golf was one of his enthusiasms, and he was also a keen salmon fisher and a lover of Deeside where he spent a month every year."

THE LATE SIR BRUCE BRUCE-PORTER

L. K. writes: "As perhaps his oldest friend I may be allowed to mourn, with many hundreds, the passing of B.-P. His vital principle was his vivid and brilliant enthusiasm for that which he believed to be right, thus he harnessed his dream of helping others to the chariot of practical endeavour. His chief characteristics were his whole-hearted devotion to his patients, regardless of all personal consideration of leisure or fatigue, and his contagious optimism. Never idle, he was always willing to help anyone over a stile and to take infinite trouble in so doing. He bore the last six months of suffering with fortitude and grace, until 'out of the stress of the doing, he has passed into the peace of the done.'"

Births, Marriages, and Deaths

BIRTHS

BLANSHARD.—On Oct. 24, in London, the wife of Dr. Paul Blanshard—a son.

BRAINES.—On Oct. 28, in Jersey, the wife of Dr. F. M. Braines—a son.

BRAND.—On Oct. 22, at Vellore, India, the wife of Mr. Paul Brand, F.R.C.S.—a daughter.

ELLIOTT.—On Oct. 24, at Reading, to Dr. Katherine Elliott, wife of Mr. A. M. Elliott—a daughter.

HOLMES.—On Oct. 25, at Edgware, the wife of Dr. S. W. Holmes—a son.

JONES.—On Oct. 29, at Morden, the wife of Dr. G. Lewis Jones—a daughter.

KELLY.—On Oct. 28, at Cheam, the wife of Mr. Patrick Kelly, F.R.C.S.—a daughter.

LOGIE.—On Oct. 26, at Aberdeen, the wife of Mr. N. J. Logie, F.R.C.S.—a daughter.

LOW.—On Oct. 26, the wife of Dr. M. G. Low—a son.

MASON.—On Oct. 13, the wife of Dr. H. A. C. Mason—a daughter.

NICHOLSON.—On Oct. 30, at Harrogate, the wife of Dr. B. Clive Nicholson—a son.

RICHARDS.—On Oct. 20, at Tripoli, the wife of Major H. J. A. Richards, R.A.M.C.—a daughter.

SCOTT.—On Oct. 25, in London, the wife of Dr. Oliver Scott—a daughter.

WHITTAKER.—On Oct. 24, to Dr. Margaret Morgans, wife of Dr. Norman Whittaker—a son.

MARRIAGES

FAIRBURN—NICHOLSON.—On Oct. 23, at Bangor, co. Down, Ernest Alfred Fairburn, M.D., to Margret Isabel Nicholson.

HUNT—HALEY.—On Oct. 29, at Hampton, Middlesex, Jack Naylor Hunt, M.B., to Anne-Claire Haley.

DEATHS

BREWS.—On Oct. 28, in London, Richard Vincent Brews, J.P., L.R.C.P.I.

BRIND.—On Oct. 23, at Gorran Haven, Cornwall, Harry Hanslow Brind, M.R.C.S., D.P.H.

BULLMORE.—On Oct. 29, in London, Edward Augustus Bullmore, F.R.C.S.E., aged 73.

GROSSART.—On Oct. 23, Robert Kerr Grossart, M.B. Glasg., D.P.M.

MACKINNON.—On Oct. 25, in London, Donald Mackinnon, M.B. Glasg.

MITCHELL.—On Oct. 26, at Bexhill, Ernest John Drum Mitchell, M.A., M.B. Camb.

PATERSON.—On Oct. 22, at Millbrook, near Plymouth, Alexander Cowie Paterson, M.B. Aberd., D.P.H.

WENYON.—On Oct. 24, 1948, in London, Charles Morley Wenyon, C.M.G., C.B.E., M.B., B.SC. Lond., F.R.S.

Parliament

The New Session

On Oct. 26 the King opened the new session with the full splendour of ceremonial which has been in abeyance since 1938. The main legislative proposal mentioned in the Gracious Speech was, of course, the controversial Bill to nationalise sections of the iron and steel industry, but other useful and important measures foreshadowed included a Bill to establish national parks, and improvement of the law relating to footpaths and access to the countryside as well as the better conservation of wild life. A housing Bill will provide for the improvement of existing dwellings by local authorities or private owners.

No mention was made of the promised Bill to amend the National Health Service Act to meet points raised by the medical profession, but it is expected that this matter will also be dealt with during the current session. Legislation is promised modifying the constitution and powers of the General Nursing Council and to provide for the better training of nurses. This measure will follow the recommendations of the Working Party's majority report that nurses in training should have full student status, a shorter but wider training, and a 40-hour five-day training week, and that the council should be reconstituted.

To secure the supply of safer milk a Bill will be introduced compelling retailers in certain areas to sell milk of a required quality; but the pace at which this measure can be implemented will depend on how soon pasteurisation plant can be provided.

Debate on the Address

In the debate on the Address in the House of Lords on Oct. 27 Viscount SAMUEL hoped that the Government would give speedy attention to Lord Beveridge's recent report on voluntary agencies, and Viscount HALL, on behalf of the Government, agreed that this report was well worth examining. Reviewing the legislative programme of the past three years, the noble Viscount said that the new social insurance schemes were well on their way, and benefits were beginning to be realised by the people. The same thing might be said of the Health Service, for already there was abundant evidence that the scheme was working smoothly. The many prophecies of its breakdown had proved to be wrong, for over 90 % of the population had chosen doctors, and doctors had agreed to accept them.

Lord ELTON, supporting the plea for national unity in view of the international situation, suggested that a Government might shrink from some unpopular course if the consequent odium was likely to fall on it alone, and a Government which faced difficulties realistically might well be compelled to consider not "guns before butter," but at least "guns before orange juice and free spectacles." When that time came it might be easier for Ministers to take the steps which they themselves judged necessary, not by way of conflict but by way of national coöperation.

QUESTION TIME

Spectacles and Prescriptions (Cost)

Sir ERNEST GRAHAM-LITTLE asked the Minister of Health what was the cost to date of the provision of spectacles and pharmaceutical benefits, including medical prescriptions, and dental services, including the supply of dentures, under the National Health Service Act, 1946.—Mr. ANEURIN BEVAN replied: The actual payments for the provision of spectacles, including fees paid for sight-testing, and for pharmaceutical benefits including medical prescriptions, up to Sept. 30, amounted to £981,951 and £1,905,447 respectively. These figures do not include the provision of spectacles or medicines through the hospital service. The payments for dental treatment amounted to £1,232,057. This figure does not include the cost of dental treatment provided through the hospital service.

Notes and News

SOCIAL AND ECONOMIC RESEARCH

NEARLY two years ago a standing Interdepartmen Committee on Social and Economic Research was establish Mr. George North, LL.D., the Registrar-General, is the chairm and the members, who include Prof. G. A. Clark, M.D., drawn from the academic staffs of the universities and fr Government departments.

In their first report[1] the committee point out that, Governments become increasingly involved in social a economic questions, the administrator within departme has a greater need of the knowledge which social and econo research supplies. Conversely, as the area of Governm activity expands, the outside research-worker beco increasingly dependent upon the factual raw material wh departments collect for their own purposes. The commit are therefore examining the material which depart collect, the extent to which it is or can be made avail and whether there are any fields of statistical or other infor tion in which a change in present methods of collectio treatment might benefit departmental or other resea workers. Subjects on which they give their views incl the preservation of documents (and making their exist known) and the confidentiality of Government informati they believe that information of general social utility sho not be kept confidential unless there is some good reas They are already taking steps to make available to resea libraries papers which, though not confidential, are detailed or too limited in interest to justify publication. of their principal functions, they feel, is to stimulate all fo of collaboration, whether formal or informal, between departments and research *institutions*.

CHRISTMAS SEALS

A HALFPENNY doesn't seem much; yet, by means of h pence the National Association for the Prevention of Tu culosis has carried on its work for nearly 50 years. attractive Christmas seals with the double-barred Red C which are seen on so many letters and parcels at Christmas t have provided most of the association's funds, and abo quarter of a million pounds has been raised in 10 years. money is used to carry on education in the preventio tuberculosis, research, and social welfare work. In 3 y over a million booklets on such subjects as mass radiogr childhood tuberculosis, rehabilitation, and tuberculosis ma have been distributed. Nearly 138,000 copies of the NA *Bulletin*, and more than 58,000 copies of their mag *Health Horizon*, have been issued. Refresher course doctors and social workers have also been arranged. The se for Christmas 1948 are now on sale and can be obtained for per 100 from the Duchess of Portland, chairman, N.A.P. Tavistock House North, Tavistock Square, London, W.C.1.

University of London

Prof. R. W. Scarff has been appointed to the Bland-Sut chair of pathology at the Middlesex Hospital medical sch from Oct. 1. He became reader in morbid anatomy a histology at the school in 1933 and the title of professor conferred upon him in respect of his post in 1946.

The title of professor emeritus has been conferred on Alexander Fleming, F.R.S., professor of bacteriology St. Mary's Hospital since 1928, and on Sir Francis Fra professor of medicine at St. Bartholomew's Hospital (1920- and at the Postgraduate Medical School of London (1934-4

Royal Society of Medicine

At a joint meeting with the Scientific Film Association be held at 1, Wimpole Street, London, W.1, on Monda Nov. 15, at 8 P.M., Dr. Pedro Belou, professor of anatomy the faculty of medical sciences, Buenos Aires, will show films on the Neuraxis.

London School of Hygiene

The following awards have been made to students of th 1947–48 course at the school for the academic diploma public health:

Chadwick prize, Dr. P. M. Elliott; Hecht prize, Dr. G. Ladd and Dr. N. S. Hepburn; Industrial Medical Officers' prize, Dr. P. Elliott and Dr. D. F. Eastcott.

The Duncan medal in the course for the diploma in tropic medicine and hygiene was awarded to Dr. Hing-Yui Mok.

Watson, M.B. Lpool, S. P. B. Way, M.B. Lond., Whitaker, M.D. Leeds, J. B. Wild, M.B. Lond., H. B. L. L.R.C.P., I. G. Williams, M.B. Lond., F. B. M. Woodhouse, D. G. Wraith, M.B. Camb., G. A. Wright, M.B. Wales, Lond.

ces to practise were conferred upon the following 146 es (113 men and 33 women) who have passed the mination of the Conjoint Board and have complied by-laws of the college:

M. Adams, Maureen B. Adams, D. A. Ager, D. D. Alexander, xander, J. D. Arneaud, N. O. Ascroft, K. A. Baker, K. L. D. F. Bedford, D. P. Belgrave, Silvio Benaim, G. R. Elizabeth Bennett, J. M. Bernstein, A. L. Berwitz, T. B. J. A. L. Bonnell, P. H. Bracewell, A. T. Broadbridge, Brock, R. J. Carey, J. K. Carter, W. I. Carter, J. A. Cheese, M. Chippindale, Montague Cohen, W. W. H. Colmer, h D. Connan, W. E. Cooper, A. A. Craigen, Phyllis A. M. D. A. Davey, D. H. Davies, G. J. Davies, Gwenhwyfar V. J. E. Davies, Nuala M. Dowdall, R. W. Doy, Shirley R. B. H. du Heaume, Gwenllian Edwards, A. A. Eley, Mary G. H. B. F. Fairley, Jack Fine, C. A. Foster, Lois Gardiner, Gardner, G. M. Gould, A. A. Graham, Edwina E Green, A. Hahn, D. C. Hall, J. A. H. Hancock, D. F. N. Harrison, Haughton, G. E. Haward, R. B. Heisch, A. A. Hobbs, P. H. C. I. Hood, J. C. Humber, K. M. S. Hume, Marjorie J. T. E. Jeffreys, Beryl M. Joles, C. R. Jolly, D. H. Jones, Kahn, M. A. Kalina, A. J. Karlish, Mohan Singh Kataria, Ratan Ker, Eric Killey, G. S. Laing, Percy Lancer, B. H. Gerda Lewin, E. A. C. Lloyd, V. A. Lloyd, Mary Lloyd- F. A. H. Logie, R. H. Longton, J. A. Ludwig, Bernard Elizabeth G. S. McDowall, Meherbanoo Hormasji Masina, Menon, John Monckton, D. K. Morgan, D. McK. K. Muir, Neville, W. T. Newman, Anne Nunan, H. M. C. O'Driscoll, M. Ottaway, K. L. Owen, J. J. Owles, Owen Parry-Jones, I. C. Payne, G. W. Pearce, M. C. Peterside, E. M. D. G. Price, Margaret D. E. Quinet, B. W. Richards, F. Richards, J. L. Richards, W. R. Riley, I. R. L. Rose, W. Ruscoe, D. G. Rushton, J. M. S. St. John, E. R. J. Habib Janmahomed Sayani, W. K. Schnarr, D. N. M. Scott R. G. Seager Thomas, S. A. V. Serviss, Pauline M. Seymour- P. W. Shillito, D. W. Smith, R. S. Sneath, D. H. K. Soltau, Speight, G. D. Starte, G. A. Steele, Mildred A. R. Stilson, C. Sumption, R. L. H. Tasker, D. G. Taylor, Margery W. Jindrich Tintner, D. A. T. Tizard, Jean M. Tomlinson, Trencham, S. E. Trickey, P. G. Tuffnell, R. J. Vale, Jehangir Vazifdar, Tom Wade-Evans, P. R. Wagner, Norma M. F. R. H. Wrigley, J. R. W. Wynne.

Diplomas were conferred on those named in the report the meeting of the Royal College of Surgeons in THE of Oct. 23 (p. 673). The following diplomas were conferred:

D.O.M.S.—J. S. McKenty.

D.C.H.—M. F. Moss.

D.Phys.Med.—G. H. Dobney, D. M. L. Doran, Joan M. Gold, Gregg, J. B. M. Milne, K. W. N. Palmer, J. D. Thompson, R. W. Windle.

Royal College of Surgeons of Edinburgh

At a meeting of the college held on Oct. 27, the following office-bearers were elected for the ensuing year: president, Mr. Frank Jardine; vice-president, Mr. J. M. Graham; secretary and treasurer, Mr. K. Paterson Brown; councillors, Dr. G. Ewart Martin, Mr. W. Quarry Wood, Mr. Walter Mercer, Prof. J. R. Learmonth, Dr. W. F. Theodore Haultain, Mr. R. L. Stewart; representative on the General Medical Council, Sir Henry Wade; conservator of museum, Mr. J. N. J. Hartley; convener of museum committee, Mr. W. Quarry Wood; librarian, Dr. Douglas Guthrie.

The following were admitted to the fellowship:

Alexander Adam, Ghanim Yacoub Akrawi, J. L. Anderson, J. H. H. Balmer, Narendra Chandra Banerjee, Aubrey Belles, Solomon Bender, J. A. Bentham, T. A. Berry, Kalindi Ganesh Bhate, J. G. Bickerton, O. M. Brewster, D. T. A. Brown, J. C. McC. Browne, P. L. Brunnen, Samuel Burke, A. E. Burton, R. W. Busschau, T. S. Chalmers, HHimangsu Sekhar Chaudhuri, Kahan Chand Chopra, Daphne Wai Chan Chun, G. L. Clark, Harry Colman, P. U. Creighton, Kandarpa Tuljashanker Dholakia, W. A. J. Donald, J. W. Eadie, C. O. Easmon, Ahmed Fattouh Abdel Fattah, R. J. A. Fraser, J. R. Frylinck, Yogendra Lakshmidas Ganjawala, C. C. Gardner, Surajit Prosad Ghosh, I. E. W. Gilmour, M. A. Goodwin, Don F. de S. Goonawardena, Alexander Gonski, Walter Gordon, A. A. Haig, R. L. Hartley, F. J. Hedden, O. K. Hjertaas, A. R. Hodgson, J. M. Hoffman, D. W. Hulsh, Margaret A. Ingram, F. L. F. Innes, L. A. Jacobs, H. V. Jones, J. D. Joubert, C. V. Jumeaux, Rasiklal Mohanlal Kamdar, S. K. Kay, H. H. Kennedy, H. I. Le Brun, R. B. Lynn, Girija Shankar Das Mahapatra, C. B. R. Mann, W. B. Martin, Annamma Mathan, N. D. Matson, G. E. Mavor, Khushru Mancherji Mehta, B. F. Miller, R. J. V. Milner, G. P. Mitchell, Philip Moore, Salathiel Morgan, Ernest Morrison, E. L. F. McConnachie, Alasdair MacKellar, R. G. MacLeod, R. A. M. McVicker, J. D. O'Flynn, W. J. O. Page, A. T. S. Paul, A. M. Porter, Henry Proctor, Alexander Raxlen, Frank Riggall, E. L. S. Robertson, A. P. Sandrasagra, P. P. H. Schmidt, N. C. Scott, El Sayed Abdel Khalek Himmat Abou Shabanah, William Sillar, Appacutty Sinnatamby, E. W. O. Skinner, Arthur Skowron, H. A. Smith, W. F. Smyth, Ralph Spencer, H. M. Stevenson, W. B. Stirling, Bahman Sohrabji Surti, Geoffrey Sutherland, J. W. Sutherland, K. G. Symonds, L. R. Taylor, M. N. Teubes, L. W. Warcup, C. C. Wark, Samir Riad Wassef, Arthur Webb-Jones, W. F. White, A. E. Wilkinson, D. G. Wright, S. P. Wrightson.

Physiology of Vision

Prof. H. Hartridge, F.R.S., will give four lectures on this subject at Gresham College, Basinghall Street, London, E.C.2, on Monday, Wednesday, Thursday, and Friday, Nov. 8, 10, 11, and 12, at 5.30 P.M.

South East Metropolitan Regional Tuberculosis Society

The inaugural meeting of this society will be held at the County Hospital, Sevenoaks Road, Orpington, Kent, on Saturday, Nov. 13, at 11 A.M. Brigadier H. L. Glyn Hughes, senior administrative medical officer of the region, will speak, and all interested doctors in the region and particularly those engaged in chest work are invited to attend.

Retirement of Dr. Fairfield

Dr. Letitia Fairfield, whose retirement is announced, was a senior medical officer in the L.C.C. service, which she entered in 1912.

For some years, Dr. Fairfield, who is also a barrister-at-law, worked in the council's school medical service, first as assistant and later as divisional medical officer. In 1930 she was promoted to senior medical officer—the first woman to hold this rank—and since then she has been engaged mainly in the hospital and ancillary services. During the first world war she became woman medical director, Royal Air Force; and in 1919 she was appointed C.B.E. In the late war she was chief medical officer of the A.T.S. until 1942, when she reached the age-limit for this appointment.

Faculty of Ophthalmologists

On Oct. 8 the council considered the question of fees for ophthalmic examination of school-children. When it was discovered that extremely high figures were being claimed in fees for this work, the Ministry of Health, after communication with the hon. secretary of the faculty and the British Medical Association, issued a circular postponing all payments until a figure had been agreed. At a meeting of the ophthalmic subcommittee of the Negotiating Committee with the Ministry of Health it was agreed that the school medical service should come under the hospital service by March 31, 1949, and that in the meantime a fee of £6 6s. per session should be paid, subject to Treasury approval. In spite of the strong recommendations of the delegates at this meeting, the Minister remained adamant that glasses prescribed privately should not be obtained free within the service.

It has been agreed that opticians working under the Supplementary Ophthalmic Service should refer to ophthalmic surgeons all patients who do not achieve a visual acuity of 6/6.

Medical and Dental Defence Union of Scotland

In this union's report for the year ended Aug. 8, the membership is given as 6096—an increase of 191 over last year's total. Assets amount to over £37,000, representing a reserve per member of £6 2*s.* 4*d.*; and the cost per member during the year was 15*s.* 10¾*d.*, leaving a balance, out of each £1 subscription, of 4*s.* 1¼*d.*

Manchester Regional Hospital Board

On Oct. 26 the board, as reported in the *Manchester Guardian* of Oct. 27, decided to submit for the approval of the Minister of Health estimates of expenditure for 1949–50 amounting to £12,906,248. Of this sum £696,258 represents capital expenditure. Under the heading of maintenance account, the cost of the board's central administration is put at £61,500; and other direct expenditure at £784,500. Costs of central administration of hospital management committees are estimated at £235,240, and of their general maintenance at £11,128,750.

London Hospital Dinner

Presiding over the old students' dinner in London on Oct. 28, Mr. Robert Milne welcomed back the women students who had "come to the rescue" in the 1914 war, and who now attended the gathering for the first time. In a chronicle of events since the last dinner he spoke of losses to the hospital by the death of Cecil Wall, George Riddoch, and G. T. Western, and by the retirement of W. S. Herm n, Arthur Burrows, Charles Goulden, John Parkinson, H. S. Souttar, and Ashley Daly. Of retirement he remarked that when for many years one has spent three or four half-days (not "sessions") at hospital, and then stops, one can find life very pleasant. Among new appointments, he mentioned especially the return of Victor Dix to be professor of surgery, and Dorothy Russell's appointment to the chair of pathology—in succession to a man who was consecutively known as H. M. Turnbull, Dr. Turnbull, Professor Turnbull, and The Chief, and was entitled to all four names because he did four men's work. Permitting himself a single reminiscence, Mr. Milne then described a night in 1903 when Warner and Dawson's house-physician was operated on for appendicitis (he has lately written to say that he can still run after a bus) and soon afterwards a burglar had a stab wound of the heart sutured (he has lately written to say that he can still run after a bus, and catch it and has led a respectable life). People had the idea that hospitals are places to which patients go for perhaps four weeks, and then pass on; to which students go for perhaps four years, and then leave forever; a place where ships pass in the night. But this was not true: a hospital was a place of continuing friendships and lasting memories—memories of chiefs who bullied you when you were a houseman, and of housemen who bullied you when you were a chief. The London Hospital, for all its internal changes, still stood exactly where it did: and on emerging from Whitechapel station one could still detect the faint smell of coffee and human unwashedness described by Henry Bashford 38 years ago. The hospital's ambition was to produce a thoroughly sound doctor, to be depended on in emergency, who would do the right thing even if he didn't quite know why. It had produced great men of science, like Henry Head and Hughlings Jackson, but also men of great service like Barnardo and Grenfell. He had a faint fear that in the new system unselfishness and the spirit of service might be snowed under, but he asked his hearers to drink the hospital's health in the hope that they would continue.

Mr. Souttar proposed The Chairman, whom he praised as an example of something now lost—the general surgeon who has made a brilliant success as a specialist. He also mentioned qualities of character, familiar to all Mr. Milne's students, which made the response to this toast particularly warm.

Dr. R. J. Peters, deputy chief medical officer of the Department of Health for Scotland, has left for the United States where he is to attend the annual conference of the American Public Health Association. Dr. Peters will also attend, along with Dr. A. H. Gale of the Ministry of Health, a subcommittee on the control of infectious diseases set up by the committee on research and standards of the association.

CORRIGENDUM: *Dentures and Anæsthesia.*—As printed, the reference to acrylic resin in Mr. Phillips's letter last week (p. 708) was incorrect. His point was that acrylic resin is *not* opaque to X rays.

Appointments

BLAKE, H. E., M.A., B.CHIR. Camb., F.R.C.S., F.R.C.S.E.: pla surgeon, St. George's Hospital, London.
WAMBEEK, W. G. L., M.R.C.S.: airport M.O., Middlesex Con Council.

Guy's Hospital, London:
BEYNON, D. W., M.B. Lond., M.R.C.P., D.C.H.: assistant to dire of department of pædiatrics.
HAFFNER, C. E. L., M.B. Edin., D.P.M.: registrar in departmen psychological medicine.
REDMAN, E. G., M.B. Dubl., D.M.R.: registrar in department diagnostic radiology.

St. Andrew's Hospital, London:
BOLGER, J. T., M.B. N.U.I.: asst. M.O., class I.
HAMILTON, J., M.B., D.A.: senior resident anæsthetist.

Diary of the Week

NOV. 7 TO 13

Monday, 8th

ROYAL COLLEGE OF PHYSICIANS, Pall Mall East, S.W.1
5 P.M. *Mr. R. M. B. MacKenna: Dermatology in its R* to General Medicine. (Part I.)
ROYAL COLLEGE OF SURGEONS, Lincoln's Inn Fields, W.C.2
3.45 P.M. Prof. G. A. Mitchell: Autonomic Nervous Syst
5 P.M. Mr. R. J. Ludford, D.SC.: Malignant Growths in Culture.
MEDICAL SOCIETY OF LONDON, 11, Chandos Street, W.1
8 P.M. *Pathological meeting.*

Tuesday, 9th

ROYAL COLLEGE OF PHYSICIANS
5 P.M. Dr. J. Purdon Martin: Local Lesions of the Cord. (Part I.)
ROYAL COLLEGE OF SURGEONS
3.45 P.M. Prof. John Kirk: *Topographical Anatomy* Thorax.
5 P.M. Dr. J. E. Cates: Renal Function.
INSTITUTE OF DERMATOLOGY, 5, Lisle Street, W.C.2
5 P.M. Dr. Harold Corsi: Scars.
INSTITUTE OF LARYNGOLOGY AND OTOLOGY, 330, Gray's Inn W.C.2
11.30 A.M. Dr. T. S. Littler: Physical Principles of Audio and Hearing-aids.
2.15 P.M. Dr. E. H. R. Harries: Respiratory Tract in Infe Diseases.
CHELSEA CLINICAL SOCIETY
7.30 P.M. (South Kensington Hotel, 47, Queen's Gate Te S.W.7.) Mr. John Hanby, F.I.S.CH.: Value of Chir in Foot Disabilities.

Wednesday, 10th

ROYAL COLLEGE OF PHYSICIANS
5 P.M. Dr. W. D. W. Brooks: Recent Advances in Treatment of Pulmonary Tuberculosis. (Part I.)
ROYAL COLLEGE OF SURGEONS
3.45 P.M. Dr. Cates: Renal Function.
ROYAL INSTITUTE OF PUBLIC HEALTH AND HYGIENE, 28, Port Place, W.1
3.30 P.M. Dr. N. L. Lloyd: Placing the Impaired Work Industry.
ROYAL FACULTY OF PHYSICIANS AND SURGEONS, 242, St. Vi Street, Glasgow
5 P.M. Prof. D. M. Dunlop: Clinical Use of the Anti-hista Drugs. (Finlayson lecture.)

Thursday, 11th

ROYAL COLLEGE OF PHYSICIANS
5 P.M. Dr. W. H. Sheldon: Tuberculosis in Childhood.
ROYAL COLLEGE OF SURGEONS
3.45 P.M. Professor Kirk: Anterior and Posterior Abdon Walls.
5 P.M. Mr. L. E. C. Norbury: Proctology Throughout Ages. (Bradshaw lecture.)
INSTITUTE OF NEUROLOGY, National Hospital, Queen Sq W.C.1
5 P.M. Prof. W. E. Le Gros Clark, F.R.S.: Olfactory Sy and the So-called Rhinencephalon.
INSTITUTE OF DERMATOLOGY
5 P.M. Dr. L. Forman: Pruritus.
HONYMAN GILLESPIE LECTURE
5 P.M. Dr. T. A. H. Munro: Diagnosis and Treatment Depression. (Edinburgh Royal Infirmary.)

Friday, 12th

ROYAL COLLEGE OF PHYSICIANS
5 P.M. Dr. Purdon Martin: Local Lesions of the Sp Cord. (Part II.)
ROYAL COLLEGE OF SURGEONS
3.45 P.M. Dr. H. G. Hanley: Micturition.
5 P.M. Dr. H. F. Brewer: Blood Transfusion.
ROYAL MEDICO-PSYCHOLOGICAL ASSOCIATION
2.15 P.M. (26, Portland Place, W.1.) Mr. Claud Mullins, J. Psychiatry in the Criminal Courts. (Maudsley lecture.)
LONDON CHEST HOSPITAL, Victoria Park, E.2
5 P.M. Dr. R. Sleigh Johnson: Acute Respiratory Infection

THE PERIOD OF TRANSMISSION IN CERTAIN EPIDEMIC DISEASES

AN OBSERVATIONAL METHOD FOR ITS DISCOVERY

R. E. HOPE SIMPSON
M.R.C.S.

om the Epidemiological Research Unit (M.R.C.), Cirencester, Glos

FOR the effective practice of public-health measures is important to discover (1) when and for how long any case of infection a communicable disease may be turally transmitted to other persons; (2) the range variability of this infective period; and (3) the ximal error of the method used.

A single over all measurement including all three factors required, and this paper seeks to show how the simple ervational methods practised by Budd and by Panum d Manicus in the nineteenth century, and by Pickles d others more recently, can provide this information certain sorts of epidemic disease.

The method is based on the information derived from o types of measurement: (1) the time elapsing between eipt of infection and manifestations of illness—the ubation period—and (2) the time between the illness one patient and the illness of those he has infected the serial interval.

A hundred years ago Panum[1] stated clearly the plest relationship of these two measurements—that, ere they are equal, transmission is taking place at the e of the manifestations of illness.

> "If it is now regarded as a rule that the contagion of sles requires between thirteen and fourteen days after reception into the organism to develop the exanthem" e., the incubation period=13–14 days—"and, as merous experiences show, that there are usually thirteen fourteen days between the time at which the exanthem ars on the patient and that at which it breaks out on fected associates"—i.e., the serial interval=13–14 days is then clear that the persons who are infected by him the contagion into their organisms at precisely the hen the exanthem is breaking out on him."

um does not pursue the significance of the relation- where the measurements are not equal, and at appears to confuse the two, an easy enough con- which the literature of epidemiology shows to be not uncommon. Later records do not altogether port his observation of the identity of the incubation od and the serial interval in measles, and it is a dy of the differences between the two which can eal the position, duration, and variability of the od of transmission.

The underlying principle is simple. The serial interval disease with direct case-to-case transmission repre- ts the interval from receipt of infection in one patient the transmission of infection to others. The incuba- period is the interval from receipt of infection to elopment of the symptoms of illness. The relationship ween the two therefore fixes the time of transference the infection in relation to the symptoms of illness of first patient.

An illness may last a long time, and for the sake of cision some particular manifestation of the disease st be selected for the purposes of measurement, and re is an obvious advantage in measuring both the ubation period and the serial interval from the same nifestation. In this way, where one person has ected another, three points of time only will be olved:

A, receipt of infection by case 1
B, transmission of infection from case 1 and receipt of infection by case 2
C, the manifestation used as a measurement.

The serial interval (indirectly) measures AB. The incubation period measures AC. It is simple to subtract the incubation period from the serial interval and so find BC, the interval between the chosen manifestation and the transference of the disease. It is well at the outset to be rid of any preconceptions about where, in relation to the clinical illness, the period of transmission will be discovered.

A very variable incubation period will introduce a factor which might well dwarf the period of transmission and stultify the practical utility of the method. The constancy of the incubation period depends on the stability in the cycle of the illness of the manifestation chosen for measurement, and the methods of making a wise choice are fully discussed below. Those acute exanthems which appear in successive crops of cases at a more or less constant interval clearly possess relatively small variability of their incubation period, and form suitable subjects for study by the present method. Nevertheless some symptoms in measles, for example, are far more variable in the time of their appearance than are others, and Panum commented on the stability of the time of appearance of the rash compared with that of the first onset of illness, and he chose the time of emergence of the exanthem as the manifestation for measurement of the incubation period and the serial interval.

NOMENCLATURE AND SYMBOLS

Epidemiological studies are often difficult to compare, even when they are similar, because of differing interpretations of the technical terms in use. For precision and comparability it has been thought necessary to define certain terms used here. The definitions are not claimed as final or universally applicable. The want of a nomenclature agreed by epidemiologists is, however, so pressing that it is to be hoped that one will not be long in appearing.

Study of the principle outlined above leads to a recognition of certain relationships which can most clearly and briefly be represented symbolically and mathematically. The following symbols will therefore be used:

d, point of measurement for a case
D, point of measurement for a group of related cases
K, serial interval
K′, median of individual values of K
k, range of variation of K
X, incubation period
X′, median of individual values of X
x, range of variation of X
Y, time elapsing between receipt of infection in receptor case and point of measurement d in donor case
Y′, interval between mid-point of period of transmission and measuring-point d
y, duration of period of transmission.

For comparison with other work, synonyms taken from epidemiological literature are supplied, and the reason is sometimes given for the choice of the preferred name. Inappropriate terms, if much used, have been included as "synonyms" of the correct term, with a note of the error.

A communicable disease is an example of host-parasite relationship and, from the viewpoint of the invading organism, is a part of the cycle of parasitism.

> *Cycle of parasitism* (cycle of the infection): the natural history of an infecting organism, including means of access to and entrance into the human host, migrations, abodes, and morphological changes in the host tissues, means of egress, and transmission directly or indirectly to other human hosts, the biology of any intermediate stages, and the behaviour and destiny of any of the organisms remaining in the host after the period of transmission.

The necessities of reproduction and species-survival are closely linked with the phenomena of human illness,
